Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assumes any liability for any injury and/or damage to persons or property arising out or related to any use of the material contained in this book.

DEDICATED TO

Anita and Claudette
our lifelong confidantes,
who keep us focused on the true importance of our existence

and

Ellen and John Stick
my parents (IAS),
for their unconditional encouragement to achieve
and –vibrant as ever in their mid-eighties- for setting an example
of how we should live through their zest for life

and

Renato, Meghan and Mary Katherine
our grown children, for making it all worthwhile

Since the publication of the first edition in 1992, *Equine Surgery* has been accepted as a definitive clinical reference and teaching text. Like the first two editions, the third edition of the book has been prepared as a foundation text for the art and science of modern equine surgery. Our intent was to produce a comprehensive textbook that would be of practical help to general practitioners, as well as provide specialists and surgeons in training with a single reference source on equine surgery. Accordingly, this third edition of the book has been significantly enlarged and includes new information, new authors, additional illustrations, and many more line drawings and tables.

The task of reviewing the ever expanding literature into concise chapters was considerable. As the editors, we divided the responsibility for organizing the sections and inviting authors between the two of us; and, we believe that the outcome is consistency of content and presentation in the final text. Additionally, we deliberately avoided omitting well-known material and concentrating only on state of the art techniques and procedures. We felt it was important that students, practitioners, and clinicians have a comprehensive textbook, discussing all aspects of this exciting field in-depth, while staying current with new developments.

All chapters in the third edition have been completely revised and updated. Many new chapters were added in areas of this discipline that are rapidly expanding. While many authors remained the same, many new authors have been added to this text, and we are indebted to all contributing authors who helped us produce this book in a timely fashion. We especially would like to thank David Freeman, Anton Fürst, Susan Holcombe, Pete Knox, Wayne McIlwraith and Rolfe M. Radcliff who provided a critical review of the second edition, making suggestions for revision and improvement of the third edition of this text. We are also indebted to the staff of Elsevier, including Elizabeth Fathman, Jolynn Gower (our most pleasant and constant contact), John Dedeke, and especially John Casey (for his tireless quest to keep the project on time and the editors happy). Personal thanks to our administrative assistants, Monika Gutscher (Zurich) and Martha Devlin (East Lansing), without whom our lives would have been much more complicated during the compilation of this book. A special thank you goes to Mathias Haab of Zurich, Switzerland, who did an excellent job in preparing all new art work and in a most efficient manner. Finally, our most sincere thanks to all the specialists who contributed to this textbook, but most especially to the Diplomates in the American and European Colleges of Veterinary Surgery for their outstanding educational contributions.

Jörg Auer and John Stick, Editors
We commonly think of shock as an event that follows severe hemorrhage or endotoxemia and causes tachycardia, tachypnea, hypotension, depression, and abnormal mucous membranes. The clinical signs of shock reflect hemodynamic responses that are the result of exquisitely controlled neurohumoral mechanisms triggered by depletion of effective circulating volume. Shock results from any inciting event that causes blood flow and oxygen delivery to be insufficient to meet the oxygen demands of the tissues. Decreased blood flow can occur because of inadequate cardiac function, decreased total blood volume, inappropriate distribution of blood volume, or obstruction of cardiac output, all of which result in decreased cardiac output and poor tissue perfusion. Because oxygen is not stored in tissues, the rate of oxygen uptake from the capillaries must match the metabolic requirements of the tissues for aerobic metabolism to continue. When metabolic demand for oxygen exceeds the rate of oxygen uptake by the tissues, anaerobic metabolism ensues, resulting in decreased energy production. When cell dysxia (the condition in which energy production is limited by the supply of oxygen) produces a measurable change in organ function, the condition is commonly known as shock. If left untreated, progressive tissue hypoxia leads to altered cellular metabolism, cell death, organ failure, and, ultimately, the death of the animal.

Understanding the pathophysiology of shock is essential for developing appropriate treatment strategies and monitoring techniques for the shock patient. As well, several aspects of the patient’s response to treatment are relevant to predicting outcome. These topics are addressed here.

### CLASSIFICATION OF SHOCK

Historically, shock has been classified on the basis of the cause of the impaired circulating blood volume. These causative categories include cardiogenic (caused by primary cardiac dysfunction), hypovolemic or hemorrhagic (due to severe blood or volume loss), distributive (resulting from maldistribution of blood flow caused by sepsis, endotoxemia, or trauma), and anaphylactic or neurogenic shock. Each of these categories ultimately results in insufficient cardiac output and impaired tissue perfusion. Shock may also be classified by functional categories that describe the type of effective blood volume depletion responsible for circulatory failure. These functional categories include cardiogenic, hypovolemic, and maldistribution shock. Finally, a third classification encompasses vasogenic and obstructive forms of shock. Hypovolemia can result from whole blood loss, fluid loss because of severe dehydration, or intestinal hypersecretion. Sepsis, endotoxemia, and anaphylaxis are causes of vasogenic shock, as they lead to maldistribution of blood flow as a result of vasodepressing substances that cause extensive vasodilation and impair appropriate venous or arterial constriction. Anaphylactic shock occurs because of an IgE-mediated release of vasodepressing substances that produce massive vasodilation and pooling of as much as 60% to 80% of circulating volume. Obstructive shock is caused by something that impedes cardiac output, such as cardiac tamponade. Frequently, disease processes cause more than one type of shock to develop in a patient. For example, a horse may lose 30% of its blood volume and develop hypovolemic shock. Because of hypoperfusion of the gastrointestinal tract and the resultant mucosal ischemia, bacterial translocation and absorption of endotoxin may occur, causing the horse to develop signs of endotoxemia. On the other hand, a horse with acute large colon volvulus may become endotoxemic but also hypovolemic as a result of hypersecretion into the gastrointestinal tract.

The depletion of circulating blood volume caused by primary blood loss can be understood intuitively. Hypovolemia caused by gastrointestinal diseases and endotoxemia is more complex. Major fluid shifts with abdominal disease occur because of hypersecretion into the bowel lumen or peritoneal cavity as a result of bacterial toxins, or because of primary endotoxemia. Frequently, both occur. These fluid shifts occur at the expense of the plasma volume, resulting in hemoconcentration and decreased circulating volume. Endotoxins have profound effects on the distribution of fluid and can cause redistribution of up to 20% of the plasma volume into the splanchic capillary beds. In addition to sodium-rich fluid losses, increased capillary permeability leads to loss of albumin and water into the interstitium, further depleting the plasma volume and reducing the intravascular oncotic pressure. Therefore, although plasma volume is retained within the horse, it is distributed into the interstitium and the gastrointestinal tract, and pooled in the venous circulation.

Classifications of shock are useful for understanding the pathophysiology of shock. They may help direct treatment...
strategies, but shock is a dynamic process and several causes of shock may develop in one patient. The result is a hypoperfused patient with inappropriate oxygen delivery to and uptake by the tissues.

**PATHOPHYSIOLOGY**

The initial response to depletion of the effective circulating volume is the movement of fluid from the interstitium into the capillaries. This transcapillary refill helps maintain blood volume but leaves an interstitial fluid deficit. This may be the only response to mild acute hemorrhage (i.e., less than 15% blood volume loss) or volume loss. The interstitial volume is then replaced by increased oral intake of water, stimulated by increased plasma osmolarity.6

Clinical signs of volume depletion occur when 15% to 20% of the circulating blood volume is lost acutely.6 This degree of blood loss causes decreased cardiac output and arterial pressure because of the relationship described in the following equation:

\[
\text{Mean arterial pressure} = \text{cardiac output} \times \text{systemic vascular resistance.}
\]

Therefore, the reduction in cardiac output lowers the systemic blood pressure. Decreased systemic blood pressure causes decreased tension in the vascular walls, initiating neurohumoral responses in an attempt to increase intravascular volume and cardiac output.7 Baroreceptors in the aorta and carotid arteries sense decreased stretch of the vascular walls, resulting in a change in baroreceptor afferent discharge to the vasomotor centers in the brain stem (Fig. 1-1). This signal is sent via branches of the glossopharyngeal and vagus nerves (cranial nerves IX and X) to the medulla oblongata, which induces sympathetic inhibition of parasympathetic stimulation.7 The catecholamines epinephrine and norepinephrine are then released from the adrenal medulla, leading to arterial and venous constriction in an attempt to improve cardiac preload. Direct arteriolar constriction increases systemic vascular resistance, thereby elevating the systemic blood pressure toward normal. Venous constriction increases blood delivery to the heart, because about 70% of the vascular volume is normally contained within the venous system.7 Myocardial contractility and heart rate are increased, which, in combination with the enhanced venous return, raises the cardiac output. Effective circulating volume depletion sensed at the carotid sinus baroreceptors also stimulates release of antidiuretic hormone from the paraventricular nuclei of the hypothalamus and ultimately from the pituitary gland, leading to increased water reabsorption at the collecting tubules of the kidney in an attempt to preserve circulating volume.7

The kidney also has an intrinsic set of mechanisms to monitor and affect blood pressure. Reduction in circulating volume is sensed by baroreceptors in the wall of the afferent arteriole and the cells of the macula densa in the early distal tubule of the kidney.8 The afferent arteriole of each glomerulus contains specialized cells—the juxtaglomerular cells—that synthesize the precursor prorenin, which is cleaved to the active proteolytic enzyme renin. Active renin is then stored in and released from secretory granules.8,9 Renal hypoperfusion (resulting from hypotension or volume

---

**Figure 1-1.** Sympathetic response to hypotension. (From Rudloff E, Kirby R: Vet Clin North Am Small Anim Pract 24:1016, 1994.)
depletion), increased sympathetic activity, and release of catecholamines are the major physiologic stimuli to renin secretion. Renin initiates a sequence of steps that begins with cleavage of angiotensin I from angiotensinogen produced in the liver and other organs including the kidney. Angiotensin I is then converted into angiotensin II, catalyzed by angiotensin-converting enzyme, which is located principally in the lung. Most angiotensin II formation takes place in the pulmonary circulation. Angiotensin II promotes renal sodium and water retention and therefore expansion of the plasma volume and ultimately the interstitium. This occurs by at least two mechanisms:

1. Direct stimulation of sodium reabsorption in the early proximal tubule
2. Increased secretion of aldosterone from the adrenal medulla, which also enhances sodium and water conservation by the kidney

Angiotensin II also stimulates systemic vasconstriction.

In addition to using multisignals to maintain circulating volume, the animal also responds to shock by mobilizing body reserves for increased metabolic demand. Increased circulating catecholamines and adrenocorticotropic hormone released from the hypothalamus in response to hypovolemia and hyperosmolality result in cortisol secretion from the adrenal glands. Cortisol mobilizes substrates for energy production by stimulating gluconeogenesis and protein synthesis by the liver in an attempt to meet the increased energy demands of the system during the early shock state.

These neurohumoral responses result in a hyperdynamic state that attempts to restore circulating volume and cardiac output. Although these adaptive effects are beneficial, especially in minor insults, peripheral vasconstriction leads to maldistributed microcirculatory flow with localized areas of hypoperfusion and tissue hypoxemia. During early shock, blood flow is maintained to the heart and brain at the expense of the intestinal tract, skeletal muscle, and other organs. Indeed, normal arterial blood pressure is maintained even when there is observed blood loss, meaning that some organ somewhere is underperfused because of vasconstriction of its vascular bed. Without aggressive therapy, the patient in a hyperdynamic, compensatory phase of shock begins to decompensate. When tissue oxygen consumption becomes supply dependent, anaerobic metabolism ensues, resulting ultimately in lactic acidosis, cell death, and organ failure. Decreased gastrointestinal perfusion causes decreased mucosal integrity and increased absorption of bacteria and endotoxin, overwhelming the liver’s capacity to detoxify the blood. The pancreas releases myocardial depressant factor, which decreases heart rate and contractility, depresses the reticular endothelial system, and decreases the afferent arteriole and glomerular filtration rate, leading to decreased urine production and ultimately to anuria. Ultimately, autoregulatory escape occurs, which is an overriding of sympathetic vasconstriction resulting in organ vasodilation. This occurs because precapillary constriction leads to decreased tissue perfusion, resulting in a change from aerobic to anaerobic metabolism. As anaerobic metabolism continues, the neuroendocrine sympathetic response becomes ineffective, and dilation of precapillary sphincters with continued constriction of postcapillary sphincters occurs, leading to pooling of blood in the venules. Such secondary sequestration of blood volume in the tissues contributes to maldistribution of blood volume, but it also causes increased capillary hydrostatic pressure, leading to extravasation of water and salt and small amounts of albumin into the interstitium, further depleting the vascular volume. These changes at the capillary level contribute to the maldistribution of blood flow, or the distributive component of shock. As the decompensated phase of shock continues, the hypoxic, acidic endothelium and poorly perfused capillaries activate macrophages and leucocytes and produce cytokines, including interleukin-1, interleukin-6, tumor necrosis factor, platelet activating factor, eicosanoids, and other immunoochemical cascades, which may initiate intravascular coagulation, a state of systemic inflammation, organ failure, and death.

The common denominator in early shock is inadequate oxygen delivery. Oxygen is needed to meet normal or increased metabolic activity as measured by oxygen consumption. Two variables describe oxygen transport: the rate of oxygen delivery (DO₂) and the rate of oxygen uptake or consumption (VO₂) (Table 1-1). Delivery of oxygen to the tissues depends on cardiac output and the oxygen content of the arterial blood. Cardiac output depends on heart rate and stroke volume, which are affected by preload, afterload, myocardial contractility, and rhythm. The oxygen content of the arterial blood (CaO₂) is determined by the formula

\[ CaO₂ = (1.34 \times Hb \times SaO₂) + (0.003 \times PaO₂) \]

and is thus dependent on the amount of hemoglobin (Hb) and the oxygen saturation of the hemoglobin in the arterial blood (SaO₂). Note that the dissolved oxygen, or partial

pressure of oxygen, in the arterial blood (Pao₂) contributes very little to the oxygen content of the blood. An oxygen debt occurs when the oxygen consumption permitted by delivery is less than that needed. DO₂, the amount of oxygen delivered to the tissues per minute, is described by the formula

\[ DO_2 = CO \times CaO_2, \]

where CO is cardiac output. The amount of oxygen consumed by the tissues (VO₂) is equal to the difference between the amount of oxygen in the blood delivered to the tissues and the amount of oxygen in the blood returning from the tissues:

\[ VO_2 = CO \times (CaO_2 - Cvo_2), \]

where Cvo₂ is the oxygen content of the venous blood (see Table 1.1).

Therefore, measures of oxygen supply to the tissues, such as heart rate, cardiac output, mean arterial pressure, hemoglobin concentration, and arterial oxygen saturation, provide information on oxygen supply but not about adequacy of tissue oxygenation. If a decrease in oxygen uptake is not accompanied by a decrease in metabolic rate, oxygen supply cannot support aerobic metabolism, and anaerobic metabolism ensues. In the aerobic state, glucose is completely oxidized, yielding 36 moles of adenosine triphosphate per mole of glucose. However, when the metabolic demand for oxygen exceeds the rate of oxygen uptake by the tissues, a portion of the glucose metabolism is diverted to the production of lactate, with an energy yield of only 2 moles of ATP per mole of glucose. Therefore, blood lactate levels can help to predict tissue oxygen deficit and, combined with other evidence of inadequate oxygen consumption, can support a diagnosis of hypoperfusion, oxygen debt, and shock.

**CLINICAL SIGNS**

The clinical stages of shock include (1) the compensatory phase, sometimes referred to as the hyperdynamic phase, (2) the early decompensatory or hypodynamic phase, and (3) the terminal decompensatory phase. These phases follow the depletion of effective circulating volume, neuroadrenal responses to the depletion, and the amount of oxygen debt that is accrued. The American College of Surgeons identifies four categories of acute blood loss based on the percentage loss of blood volume:

- **Class I:** Loss of 15% or less of the total blood volume. This degree of blood loss is usually fully compensated by transcapillary refill. Because blood volume is maintained, clinical manifestations of hypovolemia are minimal or absent.
- **Class II:** Loss of 15% to 30% of the total blood volume. The clinical findings at this stage may include resting tachycardia, orthostatic changes in heart rate and blood pressure, decreased urine output, and agitated mental state.
- **Class III:** Loss of 30% to 40% of the blood volume. This usually marks the onset of hypovolemic shock, with a decrease in blood pressure and continued decreased urine output, possibly to an anuric state. There is evidence that the tachycardia-vasoconstrictor response to hemorrhage can be lost at this stage of blood loss.
- **Class IV:** Loss of more than 40% of the blood volume. This is a harbinger of circulatory collapse.

The hyperdynamic or compensated phase of shock correlates with early class II blood loss, and clinical signs of compensation begin when the blood volume is acutely depleted by greater than 15%. The initiating event is abnormal tissue perfusion followed by compensatory neurohumoral responses, which cause clinical signs such as tachycardia, tachypnea, hyperemic mucous membranes, fast capillary refill time, and bounding pulse pressure. This high-energy state is achieved by increasing the metabolic rate. If the compensatory response is unsuccessful, because of either the severity of the insult or lack of appropriate treatment, early decompensation ensues.

Early decompensation correlates with late class II and class III blood loss and begins when oxygen delivery does not meet consumptive needs, initiating anaerobic metabolism and lactic acidosis. Clinical signs of early decompensation include progressive tachycardia, tachypnea, prolonged capillary refill time, cold peripheral appendages such as ears, muzzle, and limbs, poor pulse pressure, decreased urine production, and abnormal mentation exhibited as depression or lack of responsiveness.

Late decompensation correlates with class IV blood loss and is associated with marked hypotension, bradycardia, circulatory collapse, pale to gray mucous membranes, progressive abnormal mentation or somnolence, anuria, and other evidence of organ failure. Late decompensation is a nearly lethal stage of shock, and many patients are no longer able to respond to even very aggressive therapy.

**TREATMENT**

Prompt, aggressive fluid therapy (see Chapter 3) is the hallmark of shock treatment, with the goals of resuscitation being reestablishment of oxygen uptake into the vital organs and sustained aerobic metabolism. Fluid therapy is used to restore intravascular volume, improve tissue perfusion, and overcome regional circulatory deficiencies caused by uneven, maldistributed vasoconstriction. The most commonly used fluids for volume resuscitation are balanced polyionic crystalloids, which are isotonic relative to plasma and have a similar electrolyte composition. They contain water, sodium or glucose, other electrolytes, and, in some instances, a buffer. The principal electrolyte in crystalloid fluids is sodium, which is also the main electrolyte in the extracellular fluid.

Extracellular fluid is distributed between the interstitial and intravascular fluid compartments, with the majority (75%) being in the interstitium. Therefore, within 1 hour of intravenous administration, crystalloids are distributed evenly throughout the extracellular fluid, primarily expanding the interstitial fluid space. For example, administration of 10 L of polyionic crystalloids results in an expansion of approximately 2.5 L or less in blood volume and 7.5 L of interstitial volume. A significant amount may be lost in the urine, depending on the rate of delivery.

Examples of isotonic crystalloid solutions are 0.9% NaCl, lactated Ringer’s solution, Plasma-Lyte A, and Normosol-R.
If the horse is sodium or chloride deficient, 0.9% NaCl is a good choice. Lactated Ringer’s solution contains potassium, calcium, and lactate as a buffer. Lactated Ringer’s—or any solution containing calcium—is incompatible with blood products because the calcium will bind with the citrated anticoagulant, and therefore it should be discontinued during whole blood or plasma transfusions. Normosol-R and Plasma-Lyte A are pH balanced and contain some magnesium. For resuscitation purposes, any isotonic crystalloid solution is appropriate.

To determine the volume of crystalloid fluids to administer to a patient in shock, estimate the blood volume lost; then give four times that volume because the principal distribution of crystalloids is into the interstitial space. Or, as a “shock dose,” administer 90 mL/kg at a rate of 6 mL/kg per minute while monitoring the patient closely. The horse’s total blood volume is estimated to be 0.08 to 0.09 times its lean body mass in kilograms. Therefore, a shock dose of fluids amounts to the administration of one volume of circulating blood. This is estimated to be 40 to 50 L of fluid for a 500-kg horse. Pulmonary edema from volume overload is unlikely to occur in an adult horse, but it may occur if the horse is in anuric renal failure or has pulmonary contusions or inflammation or cardiac dysfunction.

Achieving a fluid rate of 6 mL/kg per minute in an adult 500-kg horse is difficult without using automated fluid pumps, which can cause endothelial damage and vascular thrombosis. Determinants of flow through a rigid tube are based on the Hagen-Poiseuille equation: the rate of laminar flow will vary directly with the fourth power of the inner radius of the catheter (bigger is better) and streamlined flow will vary directly with the fourth power of the length (shorter is better). The rate of resuscitation can be improved by using large-bore, short catheters and large-bore extension sets and lines. Crystalloid fluids can be given at 1 L/min, or faster, through a 12- or 10-gauge catheter (Mila International, Inc., Florence, Ky.; 12-gauge, 13-cm Teflon IV catheters) using large-bore extension sets (International WIN, Ltd., Kennett Square, Pa.) with fluids elevated at least 1 m above the horse’s withers. Although the most commonly used resuscitative fluids in human and veterinary medicine are the polyionic crystalloids, hypertonic saline may be used if more rapid effective circulating volume expansion is required.

Hypertonic saline (7.5% NaCl) is given at a maximal dosage of 4 mL/kg and will increase the circulating blood volume by two to four times the volume given. Exceeding this dosage puts the patient at risk for a hyperosmolar state. Hypertonic saline is useful in severe life-threatening cases or for patients that have very painful acute abdomen and cannot be resuscitated prior to anesthetic induction. It works by shifting water into the plasma, first from red blood cells and endothelium and then from the interstitial space and tissue cells, so that, ultimately, expansion of the plasma volume occurs as a result of depletion of the intracellular volume. Advantages of hypertonic saline are that it produces (1) a rapid but transient increase in blood volume to support and improve hemodynamics and (2) hemodilution and endothelial cell shrinkage, which decrease capillary hydraulic pressure and improve tissue perfusion. Hypertonic saline is effective at expanding plasma volume, raising blood pressure, improving cardiac output, lowering systemic and pulmonary vascular resistance, and improving oxygen delivery. Improved regional tissue perfusion, decreased leukocyte-endothelial cell interaction, and decreased stickiness of leucocytes point to a potential decrease in ischemia/reperfusion injury and subsequent multiple organ failures. Because it is the osmolality and not the oncotic pressure that affects water movement in the brain, and because the blood-brain barrier is essentially impervious to sodium, hypertonic saline is an appropriate fluid to use in patients with central nervous system trauma or head injury. After initial hypertonic saline therapy, it is important to administer 10 L of balanced polyionic solution for each liter of hypertonic saline given, to reestablish the intracellular fluid deficit.

If the principal goal of fluid therapy is to restore effective circulating volume, or if oncotic pressure support is required, colloid therapy is warranted. Colloids, the principal source of oncotic pressure in the blood, are large molecules that do not pass across diffusion barriers as readily as crystalloids, if at all. Therefore, they stay in the vascular space and enhance effective circulating volume expansion, which is very useful when resuscitating the hypovolemic patient and is critical when resuscitating the hypoprothrombinemic patient. Oncotic pressure, or colloid osmotic pressure (COP), opposes hydrostatic pressure that favors the movement of water out of capillaries into the interstitium. Therefore, the ability of colloids to expand plasma volume is directly related to COP. Albumin is responsible for 75% of the oncotic pressure of the plasma, with other contributions from globulins and fibrinogen. Plasma has a COP equal to 20 mm Hg. It is an excellent source of albumin and clotting factors. As a rule of thumb, administration of 10 L of plasma to a 450-kg horse will increase its total protein by 1.0 g/dL if there are no ongoing losses.

Hetastarch (hydroxyethyl starch), the major synthetic colloid fluid used in large-animal practice, is available as a 6% solution in isotonic saline. It contains amyllopectin molecules with atomic mass units of from hundreds to millions of daltons. Colloid osmotic pressure of hetastarch is 30 mm Hg. The dosage is 10 to 20 mL/kg in horses, and it increases the vascular space by 141% of the volume administered. Hetastarch has a half-life of 25.5 hours, so the duration of volume expansion is 12 to 48 hours. Hetastarch increases the COP but not the total protein, and in fact, because of dilution, it may decrease the measured total protein. Advantages of using hetastarch to support COP are its cost (lower than that of plasma) and the lack of risk of adverse anaphylactic reactions. An additional advantage is its ability to reduce the development of multi-system organ failure in patients with shock. The iron chelator deferoxamine combines with hetastarch and attenuates the iron-dependent generation of toxic oxygen-derived radicals during reperfusion of ischemic tissue. Hetastarch can also minimize signs of reperfusion injury by decreasing the oxidant-generating enzyme xanthine oxidase. Disadvantages of its use include increased serum amylase and bleeding times. The amyllopectin molecules are cleared by amylase enzymes in the bloodstream before they are cleared by the kidney. Therefore, elevations in serum amylase are common. There is a prolongation of partial thromboplastin time when hetastarch is given at 20 mL/kg, because of the interaction with factor VIII, but there are no reports of bleeding after its administration. However, in patients
with bleeding tendencies, such as uncontrolled hemorrhage from middle uterine artery rupture, thrombocytopenia, or coagulopathy, plasma would be a better choice for volume expansion and to support or restore oncotic pressure. Frequently, both hetastarch and plasma are used in the same patient, because hetastarch can be given quickly and provides excellent oncotic pressure support and vascular volume expansion, while plasma provides albumin, clotting factors, and complement and can be administered in addition to other resuscitative therapy, after the plasma has thawed.

Because oxygen delivery is proportional to cardiac output, hemoglobin level, and oxygen saturation, it is reasonable to first increase oxygen delivery by increasing the blood volume with crystalloids and colloids. If tissue oxygenation is still insufficient, especially if substantial blood loss occurred, or if the packed cell volume drops acutely to below 20% (or chronically to below 12% to 14%) after crystalloid resuscitation, blood transfusion (see Chapter 4) is warranted. The amount of blood required can be calculated by first estimating the amount of blood lost, using the class system proposed by the American College of Surgeons discussed earlier. Practically, if the horse is tachycardic with poor pulse pressures, increased capillary refill time, cold extremities, and anuria, and there is evidence of hypovolemic shock, whole blood transfusion should be given at an appropriate dosage when systemic signs of decreased oxygen delivery are present, but overzealous use of transfusion to maintain packed cell volume is not warranted.

Concerns with blood transfusion include adverse reactions. Such reactions are seen for 10 to 15 minutes, the rate of infusion should be measured every 1 to 2 minutes during this period. Elevations in these parameters, hives, or sweating may indicate that the horse is reacting to the blood transfusion, and the transfusion should be stopped. If no signs of adverse reactions are seen for 10 to 15 minutes, the rate of administration can be increased to 15 to 25 mL/kg per hour and the horse monitored every 15 to 30 minutes.

Concerns with blood transfusion include adverse reactions, disease, and immunosuppression. Whole blood transfusion causes immunosuppression, has been shown to be positively correlated with the development of postoperative infection, and is an independent risk factor for the development of multisystem organ dysfunction, as blood leads to an imbalance between proinflammatory and anti-inflammatory mediators in people. Despite the fact that the marrow begins to increase production of erythrocytes within a few hours of the onset of hemorrhage, complete replacement of erythrocytes can take up to 2 months. Therefore, whole blood transfusion should be given at an appropriate dosage when systemic signs of decreased oxygen delivery are present, but overzealous use of transfusion to maintain packed cell volume is not warranted.

Monitoring

To determine the effectiveness of the fluid therapy on oxygen delivery and the end point of resuscitation, cardiac output and perfusion are monitored. Signs of improvement include increased heart rate, increased pulse pressure (i.e.,
the difference between systolic and diastolic pressures), increased arterial pressure, improved mentation, warming of the extremities, decreased capillary refill time, and increased urine production with decreased specific gravity. Trends in packed cell volume and total solids can be useful, especially if hemorrhage occurred or whole blood transfusion was given.

Central venous pressure (CVP) can be measured easily and provides an indication of the venous return to the heart. It is measured at the level of the right atrium by placing sterile polypropylene tubing through a 12-gauge catheter located in the right jugular vein. A three-way stopcock is attached to the tubing and to a manometer primed with heparinized saline. The manometer is zeroed by placing it at the point of the horse’s shoulder. Mean CVP in a standing adult horse is 12 cm H₂O. In hypovolemic animals or those with vasodilation, the venous return to the heart is reduced and the CVP is low and will increase with intravenous fluid therapy. The CVP is also very useful in identifying volume overload in a horse with anuric renal failure or cardiac compromise, which can result in pulmonary edema.

The mean arterial blood pressure can be monitored in standing adult horses. It is usually measured indirectly from the middle coccygeal artery, using a manometer or an electronic transducer (Dinamap Pro Series monitor, GE Medical Systems, Milwaukee, Wis.). Normal coccygeal uncorrected systolic blood pressure should be 80 to 144 mm Hg. In hypovolemic patients, indirect measurements tend to be spuriously low or at times undetectable, presumably because of peripheral vasoconstriction, and therefore indirect blood pressure monitoring in the adult horse with shock is rarely performed.

Cardiac output can be measured using indicator dilution techniques, with indocyanine green, cold (thermodilution), or lithium as the marker. Lithium dilution is the easiest and most accurate method, requiring only catheterization of a peripheral artery and a jugular vein. It has recently been validated in anesthetized adult horses and neonatal foals.

Cardiac output can also be measured using Doppler echocardiography, which is a noninvasive ultrasound-based technique. Serial measurements of cardiac output provide useful information about the patient’s response to volume resuscitation and improvement in oxygen delivery. However, hemodynamic measurements such as central venous pressure, mean arterial pressure, and cardiac output can all be improved in horses, especially after application of positive inotropic drugs, while the horse continues to suffer from hypoperfusion and remains in an anaerobic state. This is because these measurements reflect oxygen delivery to part of the horse and not oxygen consumption by the tissues.

A good method for monitoring oxygen consumption by the tissues is the measurement of blood or serum lactate. Blood lactate levels are a good indicator of perfusion; as perfusion and oxygen delivery to the tissues and oxygen utilization improve, serum lactate levels normalize. The serum lactate level may initially increase as “lactic acid washout” occurs, but with restoration of aerobic metabolism in the peripheral tissues, it should return to normal within 2 hours. Blood and plasma lactate levels are equivalent, and these values are useful in predicting outcome in patients treated for shock.

Anaerobic metabolism is not the only source of lactate. Other causes of hyperlactatemia include hepatic insufficiency and impaired clearance of lactate by the liver, thiamine deficiency as a result of blocked pyruvate entry into mitochondria, alkalosis (which stimulates glycolysis), intense muscular activity, and production by enteric microbes. In sepsis, part of the cause of lactate elevation is attributed to endotoxin. Endotoxins block the actions of the enzyme pyruvate dehydrogenase, which is responsible for the movement of pyruvate into the mitochondria. Subsequently, pyruvate accumulates in the cell cytoplasm, where it is converted to lactate. Once tissue oxygenation is restored, lactate can be used as a fuel source by tissues such as heart, brain, liver, and skeletal muscle. Other measures indicative of improved oxygen transport (in addition to normalization of blood lactate) include increased venous oxygen saturation (greater than 50%), and normalization of base excess and pH. When venous blood gases are used to measure venous oxygen saturation, the blood gas must be collected anaerobically, stored on ice, and processed quickly to minimize errors. Pulse oximetry may be used to estimate arterial oxygen saturation and calculate oxygen extraction. However, pulse oximetry is unreliable in the underperfused, hypotensive patient and must be applied to a nonkeratinized appendage, such as the tongue, which is difficult in the awake horse.

### Controlled Hypotension

Although the goal of therapy is to restore oxygen delivery and effective circulating volume with prompt, aggressive therapy, this resuscitative strategy can be deleterious to the patient if hemorrhage is not controlled. Active bleeding from an injured large vessel may be uncontrollable without surgical hemostasis, or it may stop spontaneously by vessel retraction, vasoconstriction, tamponade, or intraluminal or extraluminal thrombus formation. The hemostatic plug, which forms over several minutes, consists of platelet aggregates and fibrin mesh containing blood cells and other plasma components. Increased circulating volume and blood pressure, vasodilation, and decreased blood viscosity secondary to hemodilution—all factors associated with fluid resuscitation—can act to dislodge the hemostatic plug, precipitating continued hemorrhage. Evidence suggests that patients with uncontrolled hemorrhage have improved survival rates with controlled hypotension and mild to moderate fluid resuscitation compared with patients that received aggressive fluid resuscitation. It was proposed that in a model of vascular injury and uncontrolled hemorrhage, the hemostatic plug could be rendered ineffective because of decreased blood viscosity, dilutional coagulopathy, and “blowout” of the fibrin plug, with accentuation of ongoing hemorrhage or reestablishment of hemorrhage.

Therefore, in horses with uncontrolled hemorrhage (e.g., from middle uterine artery rupture), slower, less aggressive methods of fluid therapy may be best. There is evidence to suggest that in patients with continued hemorrhage, the best resuscitative fluid may be whole blood in addition to smaller volumes of polyionic crystalloids, because whole blood provides clotting factors, does not contribute as much to dilutional coagulopathy, and does not decrease blood viscosity. The concern with the controlled hypotensive state is, of course, underperfusion of the tissues, oxygen debt, and organ damage.
PREDICTING OUTCOME

Many human trials have shown improved survival rates, fewer occurrences of organ failure, and lower costs when cardiac output, oxygen delivery, and oxygen consumption by the tissues were promptly restored. A 92% survival rate was reached when the optimal goals were achieved within 24 hours of admission to an intensive care unit, but the mortality rate was 93% when achievement of the goals was delayed, or not reached at all, and lactate levels did not return to satisfactory levels. In patients with septic shock, blood lactate levels are closely related to survival, and decreases in blood lactate levels during the course of treatment are indicative of a favorable outcome. Base excess combined with blood lactate has been used to calculate oxygen debt and predict survival. Fortunately, such data are not available for the horse. Lack of appropriate response to aggressive resuscitative therapy is considered a poor prognostic indicator in horses. Development of organ dysfunction, such as renal failure or laminitis, after an appropriate response to aggressive resuscitative therapy is also a poor prognostic sign.

ON THE HORIZON

The rate of survival from shock will improve as detection and monitoring techniques advance, alternative crystalloids and colloids become available at reasonable cost, and hemostatic agents are developed to treat uncontrolled hemorrhage. Hetastarch has a limited role in massive resuscitation in bleeding patients because it can prolong bleeding times. A new synthetic colloid, Hextend, produces blood volume expansion without altering coagulation. Additionally, alternative crystalloid solutions, such as Ringer’s ethyl pyruvate, are being developed that expand the intravascular space and replete the extracellular fluid, but they also have anti-inflammatory properties. Coagulation factor replacement, such as recombinant activated factor VII (rFVIIa), are likely to improve survival from recalcitrant coagulopathy. After administration, rFVIIa binds to the extrinsic clotting system at the site of injury without causing systemic hypercoagulability. Finally, noninvasive monitoring techniques that would allow the clinician to better assess oxygen delivery and consumption, such as trans-thoracic electrical bioimpedance and transesophageal echocardiography, would be valuable tools in shock management. As an example, near-infrared spectroscopy, which can be used to quantitatively monitor the oxygen saturation of hemoglobin in skeletal muscle and subcutaneous tissue while simultaneously monitoring the cytochrome aa3 redox state (which reflects mitochondrial oxygen consumption), may become a clinical tool for use in the horse in the future.

Septic and Endotoxic Shock in the Horse

Pathogenesis

Sepsis refers to the systemic (and commonly overshooting) inflammatory reaction to infection, and endotoxemia refers to the presence of endotoxin in the bloodstream. The general term used to describe these systemic sequelae to inflammatory mediators is systemic inflammatory response syndrome (SIRS). During severe infection or after absorption of large amounts of endotoxin, as during acute diarrheal disease, SIRS often occurs. Septic or endotoxic shock develops when the systemic derangements compromise circulatory function.

Septic or endotoxic shock, with its serious life-threatening complications, occurs during numerous diseases in horses. Septic inflammation generally causes a local inflammatory response that complicates the function of the tissues and organs involved. However, a systemic inflammatory response occurs when the infection is local and severe (especially in adult pleuropneumonia, endometritis, peritonitis, or infectious colitis), when more than one organ is infected, or when the infection enters the systemic circulation (especially in neonatal sepsis). Infection with gram-negative bacteria is more likely to initiate SIRS because the gram-negative bacterial cell wall contains an endotoxin molecule that is a potent stimulus of equine monocytes and macrophages, resulting in synthesis and release of numerous inflammatory mediators.

The endotoxin of gram-negative enteric bacteria is a lipopolysaccharide (LPS) that is a structural component of the outer cell membrane. It is composed of three parts, each with important biologic characteristics. The inner component, the lipid-A portion, is well conserved among different species of gram-negative bacteria and imparts the toxic qualities to the endotoxin molecule. The middle region of endotoxin is the core oligosaccharide, which links the lipid-A with the outer polysaccharide portion. This core region is also well conserved in gram-negative bacteria. The outermost component is composed of repeating polysaccharides. The composition of this portion differs among bacterial species and accounts for their serologic differentiation.1

Because endotoxin is an integral component of the outer cell wall of gram-negative bacteria, it is liberated when the bacterium dies or undergoes periods of rapid proliferation. The gastrointestinal tract lumen harbors large quantities of gram-negative bacteria and free endotoxin.2 To prevent the development of endotoxemia, the horse has evolved several efficient mechanisms to restrict transmural movement of endotoxin across the bowel wall and to remove endotoxin from the portal blood.1

The mucosal epithelial cells of the intestine function as a physical barrier against transmural movement and are the first line of the innate immune response.3 These mucosal epithelial cells also secrete substances such as lysozymes, enzymes, and antibodies, which limit the ability of enteric bacteria to invade the mucosal lining. Endotoxin can traverse compromised intestinal mucosal epithelium either via transepithelial movement (transcellular) or across the intercellular tight junctions.
Sepsis refers to the systemic (and commonly overshooting) inflammatory reaction to infection, and endotoxemia refers to the presence of endotoxin in the bloodstream. The general term used to describe these systemic sequelae to inflammatory mediators is systemic inflammatory response syndrome (SIRS). During severe infection or after absorption of large amounts of endotoxin, as during acute diarrheal disease, SIRS often occurs. Septic or endotoxic shock develops when the systemic derangements compromise circulatory function.

Septic or endotoxic shock, with its serious life-threatening complications, occurs during numerous diseases in horses. Septic inflammation generally causes a local inflammatory process that compromises the function of the tissues and organs involved. However, a systemic inflammatory response occurs when the infection is local and severe (especially in adult pleuropneumonia, endometritis, peritonitis, or infectious colitis), when more than one organ is infected, or when the infection enters the systemic circulation (especially in neonatal sepsis). Infection with gram-negative bacteria is more likely to initiate SIRS because the gram-negative bacterial cell wall contains an endotoxin molecule that is a potent stimulus of equine monocytes and macrophages, resulting in synthesis and release of numerous inflammatory mediators.

The endotoxin of gram-negative enteric bacteria is a lipopolysaccharide (LPS) that is a structural component of the outer cell membrane. It is composed of three parts, each with important biologic characteristics. The inner component, the lipid-A portion, is well conserved among different species of gram-negative bacteria and imparts the toxic qualities to the endotoxin molecule. The middle region of endotoxin is the core oligosaccharide, which links the lipid-A with the outer polysaccharide portion. This core region is also well conserved in gram-negative bacteria. The outermost component is composed of repeating polysaccharides. The composition of this portion differs among bacterial species and accounts for their serologic differentiation.1

Because endotoxin is an integral component of the outer cell wall of gram-negative bacteria, it is liberated when the bacterium dies or undergoes periods of rapid proliferation. The gastrointestinal tract lumen harbors large quantities of gram-negative bacteria and free endotoxin.2 To prevent the development of endotoxemia, the horse has evolved several efficient mechanisms to restrict transmural movement of endotoxin across the bowel wall and to remove endotoxin from the portal blood.3 The mucosal epithelial cells of the intestine function as a physical barrier against transmural movement and are the first line of the innate immune response.5 These mucosal epithelial cells also secrete substances such as lysozymes, enzymes, and antibodies, which limit the ability of enteric bacteria to invade the mucosal lining. Endotoxin can traverse compromised intestinal mucosal epithelium either via transepithelial movement (transcellular) or across the intercellular tight junctions.
(paracellular). If a small quantity of endotoxin traverses the intestinal mucosal barrier and gains access into the portal circulation, Kupffer cells (hepatic macrophages) are effective scavengers of endotoxin. Additionally, many horses have small quantities of circulating antiendotoxin antibodies directed against the core region, which can bind endotoxin and facilitate its removal from the circulation.

If the integrity of the intestinal mucosal barrier is disrupted sufficiently, the quantity of endotoxin traversing the barrier may exceed the ability of these protective mechanisms to remove it from the circulation. Additionally, endotoxin can also traverse full-thickness bowel, enter the peritoneal cavity and lymphatics, and reach the systemic circulation via the thoracic duct. The permeability of the intestinal mucosal barrier is frequently increased in cases of acute equine gastrointestinal tract disease. Plasma tests positive for endotoxin in 10% to 40% of horses with colic. Increases in mucosal permeability are most often associated with ischemia/reperfusion injury caused by intestinal strangulation, severe colitis and enteritis, or gastrointestinal rupture. However, because the rate of plasma endotoxin detection is not greater in horses with these diagnoses than in horses with other causes of colic, it is concluded that endotoxia may accompany all types of gastrointestinal tract disease in horses. Endotoxin is three times more likely to be detected in the peritoneal fluid than in the plasma of horses with gastrointestinal tract disease, emphasizing that either endotoxin enters the intestinal lymphatics or it crosses the full-thickness of the bowel wall.

Once endotoxin gains access to the systemic circulation, it may become associated with high-density lipoproteins or lipopolysaccharide-binding protein (LBP), which has a strong avidity for the lipid-A region of endotoxin. This protein acts as a shuttle to transfer endotoxin monomers from the endotoxin aggregates to the surface of effector cells that subsequently respond to endotoxin. Although mononuclear phagocytes are capable of responding to endotoxin without LBP, the presence of LBP increases the sensitivity of the response for protection against gram-negative infection. The endotoxin-LBP complex transfers endotoxin monomers to a cell surface receptor antigen, known as CD14, which exists both as a membrane-bound receptor and as a soluble form in biologic fluids. The membrane-bound form is present principally on mononuclear cells, but it also exists on other cell types. The soluble form of the receptor may interact with endotoxin and LBP as well as with cells lacking membrane CD14, such as endothelial cells. The CD14 receptor plays a central role in the inflammatory cascade initiated by endotoxin. However, binding of endotoxin to this receptor alone does not result in transmission of the endotoxin signal to the interior of the cell. Thus, because the CD14 is a cell surface receptor that does not cross the cell membrane, binding of endotoxin to it does not directly initiate stimulation of second messenger systems or signal transduction pathways.

Toll-like receptors, originally identified from Drosophila, have been shown to have both transmembrane and intracellular components, which permits communication between the interior and exterior of cells. Toll-like receptor 4 (TLR4) has been shown to be responsible for delivery of the endotoxin signal from the cell surface to the interior of the cell. Stimulation of the TLR4 causes phosphorylation and subsequent degradation of the intracellular inhibitory protein IκB, resulting in the liberation of nuclear factor κB (NF-κB). This factor subsequently enters the nucleus and binds to the promoter region of genes that encode for the synthesis of inflammatory cytokines (Fig. 2-1). It has been shown that MD-2, a secreted protein that physically associates with TLR4, is required for the responsiveness of TLR4 to LPS. Additionally, MD-2 has been shown to enhance the synthesis of cytokines secondary to LPS by activating alternative pathways resulting in increased NF-κB activity.

Cytokine Activation

Cytokines (which include tumor necrosis factor-alpha [TNF-α], interleukins [IL], chemokines, and growth factors) are glycoprotein molecules that regulate inflammatory and immune responses by acting as a signal between cells. TNF-α is referred to as the proximal mediator of the response to endotoxin. Administration of TNF-α causes many of the same clinical effects that endotoxin causes. Increased plasma activity of TNF-α has been associated with increased mortality in colic and neonatal sepsis. IL-1 and IL-6 are also major proinflammatory cytokines. The following events result from endotoxin-induced cytokine synthesis:
TNF-α and IL-1 stimulate neutrophil adhesion to endothelium and activation of neutrophils.16

TNF-α causes a spectrum of changes in endothelial cells because of increased gene transcription, referred to as endothelial cell activation. In the presence of TNF-α, endothelial cells express procoagulant activity (thromboplastin or tissue factor).7,17 These responses favor hemostasis and potentiate the coagulopathy present in the systemic inflammatory response syndrome. The coagulopathy may lead to microthrombi, thereby resulting in alterations in tissue perfusion.

Activated endothelial cells also synthesize nitric oxide (NO) and eicosanoids, thereby altering blood pressure, tissue perfusion, and venous return of blood for cardiac output.

TNF-α stimulates effector cells (monocytes, macrophages, and endothelial cells) to synthesize cytokines to perpetuate the cycle of the inflammatory response.18

TNF-α, IL-1, and IL-6 stimulate prostaglandin E2 synthesis in the hypothalamus, thereby increasing the set point for body temperature, resulting in fever. These cytokines are also responsible for the altered mentation and loss of appetite that accompany the systemic responses to inflammation. Central nervous system effects of TNF-α and IL-1 result in increased release of adrenocorticotropic hormone, thereby increasing circulating corticosteroid concentrations.18

IL-1 and IL-6 induce hepatic acute-phase protein synthesis. The proteins include fibrinogen, ceruloplasmin, and α1 globulins and β globulins produced nonspecifically by the liver during inflammation. Although many of these are synthesized with no specific function, α1-antitrypsin and α2-macroglobulin are major inhibitors of leukocyte lysosomal enzymes, which help to keep in check the tissue destruction caused by enzymes released during leukocyte death.18

In addition to cytokines, other inflammatory mediators released in response to the action of endotoxin on effector cells include arachidonic acid metabolites, platelet-activating factor (PAF), oxygen-derived free radicals, NO, histamine, kinins, and complement components. The

generation of eicosanoids (cyclooxygenase enzymes), leukotrienes (lipoxygenase enzymes), and lipoxins from arachidonic acid in the cellular membrane can mediate virtually every step of inflammation. These steps involve the following agents and processes:

- Thromboxane A2 is a potent platelet-aggregating agent and vasoconstrictor.
- Increased hypothalamic synthesis of prostaglandin E2 raises the set point for body temperature.
- Leukotriene B4 (LTB4) is a potent chemotactic agent and activator of neutrophils; it causes increased aggregation and adhesion, generation of oxygen radicals, and release of lysosomal enzymes.
- Leukotrienes C4, D4, E4 (LTC4, LTD4, LTE4) cause intense vasoconstriction, bronchospasm, and increased vascular permeability (of venules).
- Lipoxin A4 stimulates vasodilation.
- Other lipoxins are potent anti-inflammatory substances.

PAF is another phospholipid-derived mediator, synthesized in platelets, basophils, neutrophils, monocytes, macrophages, and endothelial cells. Its effects are mediated via a single G protein-coupled receptor and are regulated by a family of inactivating PAF acetylhydrolases. PAF elicits most of the cardinal features of inflammation, including the following:

- At low concentrations, PAF causes vasodilation and increased venular permeability.
- At higher concentrations, PAF causes vasoconstriction, bronchoconstriction, platelet aggregation, and leukocyte chemotaxis and activation.
- PAF boosts the synthesis of eicosanoids.

**Oxygen Metabolites**

Oxygen-derived free radicals are generated in activated leukocytes through the nicotinamide-adenine dinucleotide phosphate (NADP) oxidative system, and in endothelial cells during reperfusion after ischemia via the xanthine oxidase pathway. Superoxide anion, hydrogen peroxide, and hydroxyl radical, and hypochlorous acid are the major radicals released extracellularly from leukocytes where these metabolites can combine with NO to form other reactive nitrogen intermediates (peroxynitrite) responsible for bacterial killing. Activated neutrophils adherent to endothelial cells stimulate xanthine oxidase in endothelial cells, thus causing elaboration of more superoxide. These oxygen metabolites are responsible for much of the host tissue destruction that accompanies endotoxin-induced inflammation. Oxygen metabolites also have proinflammatory functions, including the following:

- Extracellular release of low levels of oxygen metabolites can increase leukocyte adhesion and expression of cytokines to amplify the cascade of the inflammatory response.
- Endothelial cells are damaged by increasing concentrations of oxygen-derived free radicals, resulting in increased vascular permeability.
- Oxygen-derived free radicals inactivate antiproteases, enzymes that degrade the proteases released from activated neutrophils, leading to unopposed protease activity that causes destruction of the extracellular matrix.
- In high concentration, oxygen-derived free radicals lead to injury to other cell types (tumor cells, red cells, and parenchymal cells).

Nitric oxide functions not only as a mediator of inflammatory processes but also as a regulator of local blood flow and tissue perfusion. NO is synthesized by endothelial cells, macrophages, and specific neurons in the brain from L-arginine, molecular oxygen, the reduced form of NADP (NADPH), and other cofactors by the enzyme nitric oxide synthase (NOS). There are three different types of NOS: endothelial (eNOS), neuronal (nNOS), and cytokine inducible (iNOS). These types exhibit different patterns of expression. The eNOS and nNOS isoforms are constitutively expressed, resulting in low concentrations requiring increased cytoplasmic calcium ions in the presence of calmodulin. On the other hand, when macrophages are activated by cytokines via expression of iNOS, changes in cytosolic calcium are not required. NO acts on target cells through induction of cGMP (cyclic guanosine monophosphate), thereby leading to vasodilation. The in vivo half-life of NO is only a matter of seconds; therefore, the gas acts only on cells in close proximity to the site of its synthesis.

Reactive oxygen species derived from NO synthase possess antimicrobial activity. Reactions between NO and reactive oxygen species lead to the formation of antimicrobial metabolites (e.g., peroxynitrite). However, high concentrations of NO may also damage host cells. The overproduction of NO is responsible for the hypotension noted in many models of septic shock. However, endogenous control mechanisms exist for synthesis of NO in inflammatory conditions. The iNOS response does not appear to be the same in horses as in laboratory animals and humans. Plasma and urine NO concentrations do not increase significantly in horses during the 24 hours after a low dosage (35 ng/kg, IV over 30 minutes) of endotoxin is administered intravenously.

**Complement System**

The complement system consists of 20 plasma-derived proteins that modulate the systemic response to endotoxin and are directly activated by the presence of endotoxin alone and gram-negative bacteria. The result of activation of the complement system is formation of the membrane attack complex that functions in lysis of bacteria. Concurrently, the activated complement components cause increased vascular permeability, chemotaxis, and opsonization.

**Histamine**

Histamine is widely distributed in tissues throughout the body. It is preformed and stored in mast cell granules, which are normally present in the connective tissue adjacent to blood vessels. It is released during mast cell degranulation in response to activation of complement fragments (C3a and C5a) and cytokines. Histamine acts on the circulation
predominantly through H1 receptors, thereby causing dilation of arterioles and constriction of large arteries. It is the principal mediator of the immediate phase of increased vascular permeability and acts by constricting venular endothelium, causing gaps in the venular wall.

**Anti-Inflammatory Response**

Concurrent with the synthesis and release of a multitude of inflammatory mediators, sepsis and endotoxemia elicit an anti-inflammatory response designed to hold the inflammatory response in check. The LBP can serve to transfer endotoxin molecules to high-density lipoproteins, thereby decreasing the interaction of endotoxin with CD14 on inflammatory cells. Cytokine-induced endogenous glucocorticoid synthesis may inhibit further synthesis of cytokines. Interleukin-10 is an anti-inflammatory cytokine released in response to endotoxin, and its principal effect is deactivation of mononuclear phagocytes and inhibition of proinflammatory cytokine synthesis. Lipoxins generated during metabolism of arachidonic acid are potent inhibitors of the inflammatory response.

**Host Responses**

The clinical response to endotoxin may diminish with repeated exposures, a phenomenon known as endotoxin tolerance. Tolerance can also be demonstrated experimentally in vivo and in vitro with decreased synthesis of cytokines (especially TNF-α) in humans, laboratory animals, and horses. Receptor downregulation and inhibition of intracellular signaling pathways are likely mechanisms.

The host response to sepsis and endotoxemia involves defense mechanisms resulting from synthesis of inflammatory mediators and anti-inflammatory mechanisms designed to modulate the inflammatory events. Detrimental consequences occur if excessive and uncontrolled responses culminate in cardiovascular dysfunction, resulting in shock, impaired hemostasis, and organ failure. These pathophysiologic events caused by the cascade of inflammatory mediators result from leukocyte activation, endothelial dysfunction and damage, hemodynamic changes, and coagulopathy.

During sepsis and endotoxemia, cytokines activate integrins (e.g., CD11/CD18) on the surface of neutrophils, causing firm adhesion to the endothelium and leading to transmigration of neutrophils. Leukotriene B4, activated complement components, and antigen-antibody complexes stimulate activation of the neutrophil oxidative burst for bacterial killing. Xanthine oxidase–derived hydrogen peroxide reacts with large quantities of NO (generated via iNOS in neutrophils) to form peroxynitrite, a potent oxidant. Hydrogen peroxide generated in neutrophils also reacts with chloride anions, a reaction catalyzed by myeloperoxidase, resulting in the formation of hypochlorous acid, another potent oxidant. These oxidants are capable of killing bacteria and degrading endotoxin, but they are also powerful mediators of host endothelial and tissue injury.

Normal endothelium functions in the regulation of local perfusion and blood pressure, neutrophil adhesion and activation, transvascular fluid movement, and anticoagulation. Endothelial dysfunction results in a decreased responsiveness to vasodilating (vasodilating and vasoconstricting) agents, increased vascular permeability and edema, and coagulopathy. Cytokines increase expression of intercellular adhesion molecules (ICAM-1) on endothelial cells, which bind to the CD11/CD18 receptors on neutrophils, leading to neutrophil adhesion and activation. Cytokines also stimulate arachidonic acid metabolism, leading to generation of leukotrienes that alter endothelial permeability (LTC₄, LTD₄, LTE₄). Additionally, activated neutrophils release matrix metalloproteinases, which contribute to the tissue injury via breakdown of components of the basement membrane. In horses suffering from endotoxemia, extensive endothelial damage has been documented. The end result is poor tissue perfusion and edema, leading to cardiovascular shock.

In addition to the effects of endothelial dysfunction, the inflammatory mediators generated during sepsis and endotoxemia adversely affect vascular and cardiac function, leading to loss of homeostatic control mechanisms. The breakdown of hemodynamic control decreases cardiac output, venous return, and perfusion of vital organs, leading to shock. Normal blood pressure is maintained by vascular smooth muscle tone regulated by endothelial release of endothelin-1 (ET-1) (vasoconstriction), NO (vasodilation), and prostacyclin (PGI₂) (vasodilation). Horses with gastrointestinal tract disease commonly have accompanying endotoxemia and increased venous plasma concentrations of ET-1, which could reduce peripheral perfusion by vasoconstriction. Endotoxemia in horses is accompanied by increases in circulating concentrations of thromboxane, which causes pulmonary hypertension and decreased peripheral perfusion. Endothelial damage during endotoxemia impairs endothelial synthesis of PGI₂ and NO, thereby reducing local perfusion. Very high concentrations of NO generated by iNOS in macrophages lead to vascular blood pooling, and to decreased venous return and cardiac output. Sympathetic nervous system activity increases to compensate for the decreased cardiac output, resulting in tachycardia, increased stroke volume, and increased peripheral vascular resistance. Concurrent with increased ET-1, thromboxane, serotonin, angiotensin, and increased peripheral neurotransmission from sympathetic compensatory reflexes may further impair peripheral perfusion. With progression of sepsis and endotoxemia, decompensated shock results in progressive systemic hypotension caused by synthesis of excessive quantities of prostacyclin, prostaglandin E₂, and NO. Ultimately, direct myocardial suppression by NO, increased vascular permeability, impaired tissue oxygen extraction, and vascular pooling resulting from the systemic hypotension cause failure of tissue oxygen delivery and progressive metabolic acidosis.

**Prevalence and Clinical Impact**

Most respondents (73%) to a survey of diplomates of the American College of Veterinary Internal Medicine (ACVIM) and the American College of Veterinary Surgeons (ACVS) indicated that less than 25% of the horses in their practice in the year preceding the survey had evidence of endotoxemia, whereas 26% believed the prevalence was between...
25% and 50%. Over 90% of the respondents indicated they believe that enteritis/colitis, intestinal strangulation obstruction, and retained placenta/metritis were commonly associated with endotoxemia in horses, whereas between 75% and 90% of respondents believed that in their practice and in their experience, grain overload, pleuropneumonia, and laminitis were associated with endotoxemia. As many as 30% to 40% of horses admitted to university teaching hospitals for acute gastrointestinal tract disease show detectable endotoxin in the plasma and/or peritoneal fluid, and up to 50% of foals with presumed sepsis have measurable amounts of plasma endotoxin. Because the half-life of circulating endotoxin in plasma is less than 2 minutes, these results suggest that there is constant movement of endotoxin from the intestinal lumen into the circulation in horses with a compromised mucosal barrier. Most horses with gastrointestinal tract disease and endotoxemia have ischemic or inflammatory bowel disease. Therefore, the prevalence of endotoxemia is greatest for horses with intestinal strangulation obstruction (e.g., small intestinal or large colon volvulus, incarceration), enteritis (colitis, proximal enteritis), and septic peritonitis. Entrance of endotoxin into the systemic circulation results in a complex pathophysiologic cascade of events that frequently leads to morbidity and mortality despite aggressive treatment.

CLINICAL ENDOTOXEMIA AND SHOCK IN THE HORSE

Clinical Findings
Clinical signs associated with early hyperdynamic response to endotoxin include anorexia, yawning, sweating, depression, mild colic, muscle fasciculation, recumbency, increased heart and respiratory rates, mucous membrane hyperemia, decreased borborygmi, and accelerated capillary refill time. Clinical signs observed during the later hypodynamic phase of endotoxemia include brick-red to purple mucous membranes, development of a "toxic ring" around the gum line of the oral mucous membranes, prolonged capillary refill time, decreased arterial pulse strength, tachycardia, tachypnea, hypothermia, decreased venous filling, and scleral reddening (Box 2-1). More subtle signs may occur in horses in which a relatively low level of endotoxin gains access to the systemic circulation, or early in the disease process; these include mild or moderate abdominal pain, anorexia, and depression.

Assessment and Diagnostic Approach
The diagnostic approach to endotoxemia in horses includes performing a thorough physical examination, complete blood count, and arterial blood gas analysis. Complete blood count often reveals leukopenia, neutropenia, and a left shift, which is followed by leukocytosis and neutrophilia if the horse survives. An arterial blood gas usually reveals arterial hypoxemia. Horses often develop an early hyperdynamic (systemic arterial hypertension) followed by a more prolonged hypodynamic (hypotension) phase. Horses often develop pulmonary arterial hypertension. A tentative diagnosis of endotoxemia is usually made based upon the clinical signs, clinicopathologic data and the most likely primary disease process. Treatment is often necessary and should be instituted without a definitive diagnosis. Regarding the diagnosis of endotoxemia, most respondents to a survey indicated that neutropenia (94%), oral mucous membrane hyperemia (89%), leukopenia (89%), the appearance of toxic neutrophils and a left shift on the differential white blood cell count (86%), tachycardia (77%) and fever (76%) were clinical indicators of endotoxemia. Other clinical or laboratory findings listed by respondents as indicators of endotoxemia included prolonged capillary refill time (61%), coagulation abnormalities (60%), bacterial growth on blood culture (39%), any other mucous membrane.

**BOX 2-1. Diagnostic Findings for Horses with Sepsis or Endotoxemia**

**PHYSICAL EXAMINATION**
- Early Hyperdynamic Phase
  - Anorexia
  - Yawning
  - Depression
  - Sweating
  - Mild colic
  - Muscle fasciculation
  - Recumbency
  - Tachycardia
  - Tachypnea
  - Fever
  - Mucous membrane hyperemia
  - Decreased gastrointestinal borborygmi
  - Accelerated capillary refill time

- Later Hypodynamic Phase
  - Tachycardia
  - Tachypnea
  - Discolored mucous membranes
    - Brick red to purple color
    - Development of a toxic ring around gum line
  - Prolonged capillary refill time
  - Decreased arterial pulse strength
  - Hypothermia
  - Decreased venous filling
  - Scleral reddening

**COMPLETE BLOOD COUNT**
- Early Leukopenia
  - Neutropenia
  - Left shift

- Later Leukocytosis
  - Neutrophilia

**ARTERIAL BLOOD GAS ANALYSIS**
- Early arterial hypoxemia
- Hypocapnia due to tachypnea
- Later metabolic acidosis

**SERUM ENDOTOXIN OR INFLAMMATORY MEDIATOR CONCENTRATIONS**
- Lipopolysaccharide (endotoxin)
- Tumor necrosis factor-α
- Interleukin-1
- Interleukin-6
abnormality (32%), increased blood lactate or anion gap concentration (33%) and endotoxin detected on an endotoxin blood assay (21%).

Clinical Management

Treatment

The principal treatments for horses suffering from endotoxemia include (1) prevention of movement of endotoxin into the systemic circulation by the treatment or resolution of the primary disease process, (2) advanced medical and supportive care, (3) neutralization of endotoxin before it interacts with effector cells, (4) prevention of the synthesis, release, or effects of proinflammatory mediators, and (5) prevention of endotoxin-induced cellular activation (Box 2-2).

To a survey about treatment of horses with endotoxemia, respondents indicated that they administer intravenous fluids (100%), low-dose flunixin meglumine (86%), broad-spectrum antimicrobials (85%), hyperimmune antiendotoxin plasma or serum (64%), high-dose flunixin meglumine (60%), dimethyl sulfoxide (41%), hypertonic saline solution (38%), heparin (31%), normal equine plasma (29%), phenylbutazone (23%), aspirin (14%), pentoxifylline (12%), ketoaprofen (8%), and corticosteroids (8%).

BOX 2-2. Principles of Treatment for Horses with Sepsis or Endotoxemia

CONTROL PRIMARY DISEASE
- Administer laxatives or emollients
- Mineral oil
- Activated charcoal
- Di-tri-octahedral smectite
- Surgical resection of compromised bowel
- Resect or drain localized areas of infection (umbilicus, pleural/peritoneal cavity)
- Antibiotic treatment

ADVANCED MEDICAL AND SUPPORTIVE CARE
- Intravenous fluid therapy
- Crystalloids
- Colloids
- Acid-base and electrolyte correction
- Broad-spectrum antibiotics
- Plasma

NEUTRALIZE CIRCULATING ENDOTOXIN
- Hyperimmune serum or plasma
- Polymyxin B
- Phospholipid emulsion

INHIBIT INFLAMMATORY MEDIATOR SYNTHESIS
- Nonsteroidal anti-inflammatory drugs
- Pentoxifylline
- Dimethyl sulfoxide
- Corticosteroids

INTERFERENCE WITH CELLULAR ACTIVATION
- Nontoxic lipopolysaccharide or lipid-A compounds

CONTROLLING THE PRIMARY DISEASE

Addressing and resolving the primary disease is one of the most important initial aspects of treatment or prevention of endotoxemia in horses. When the primary disease is of the gastrointestinal tract, this often involves administering mineral oil, activated charcoal, or DTO (di-tri-octahedral) smectite to horses with grain overload or enterocolitis, surgically resecting ischemic bowel, or providing supportive care to horses with inflammatory bowel disease. When it is bacteremia or septicemia or localized areas of infection (e.g., pleuropneumonia, umbilical abscess), treatment involves removal of the source (pleural drainage, ophthalmoplegic lymphoma) and antibiotic treatment. In mares with retained placenta and metritis, facilitating passage of the placenta, uterine lavage, and antibiotic treatment are indicated.

ADVANCED MEDICAL AND SUPPORTIVE CARE

Supportive care involves administration of IV fluids (crystalloids and colloids) to correct dehydration and volume depletion, and to keep up with ongoing losses (diarrhea, reflux, pleural or peritoneal fluid accumulation). Correction and maintenance of electrolytes and acid-base balance is also important (see Chapter 3). Administering broad-spectrum antibiotics is important in treating horses with septic processes; however, rapid death of gram-negative bacteria could theoretically lead to increased release of endotoxin from their cell walls. It has been shown in an in vitro model of septicemia in foals that amikacin or amikacin combined with ampicillin is less likely to induce endotoxemia and TNF-α synthesis during bactericidal treatment for Escherichia coli septicemia, compared with β-lactam antibiotics such as ampicillin, imipenem, and cefotiofur. Administration of plasma is useful to help replenish plasma proteins, especially albumin, which helps maintain the necessary oncotic pressure to keep fluids in the intravascular compartment. Neonatal foals with failure of passive transfer should be administered regular plasma to increase circulating immunoglobulin levels.

NEUTRALIZING CIRCULATING ENDOTOXIN

Hyperimmune serum or plasma can be administered intravenously to horses with endotoxemia and to those predisposed to developing endotoxemia. These products are most likely to be beneficial if administered before the endotoxin gains access to the circulation, because these antiendotoxin antibodies presumably exert a protective effect by forming complexes with endotoxin before they interact with inflammatory cells. The proposed protective mechanisms of action associated with binding of the antibodies with LPS include steric blockage of interaction between lipid-A and cellular receptors, and enhanced bacterial clearance via opsonization. Although there are controversial and contradictory results using these hyperimmune plasma or serum products in experimental and naturally acquired endotoxemia, there may be a place for them in the therapeutic regimen of horses with, or predisposed to develop, endotoxemia.

There are anecdotal reports that administration of 0.5 to 1.0 L of hyperimmune serum or plasma raised against a rough mutant of E. coli (15) or Salmonella typhimurium may have fairly profound protective effects in individual horses, depending on the timing of administration and the
magnitude of endotoxemia. In a double-blind clinical study performed on horses with clinicopathologic evidence of endotoxemia, treatment with J5 hyperimmune plasma was associated with an increased survival rate (87% versus 53%), improved clinical appearance, and a shorter hospitalization period compared with horses treated with nonspecific hyperimmune plasma. However, in another study of sublethal experimental endotoxemia, J5 hyperimmune serum administration did not improve clinical or clinicopathologic variables. Additionally, pretreatment with 1.5 ml/kg of *Salmonella typhimurium* antiserum administered IV to 3- to 5-month-old foals before challenge with 0.25 µg/kg *E. coli* LPS had no positive protective effect. It was suggested that under certain circumstances, this antiserum could exacerbate the actions of endotoxin.

Forty-five percent of respondents to the previously mentioned ACVIM and ACVS survey answered that they believed administration of hyperimmune antiendotoxic plasma or serum was effective in decreasing the signs of endotoxemia, 45% were uncertain whether there was any beneficial effect, and 10% indicated they believed these products were not useful and could possibly be the cause of subsequent development of laminitis. Most respondents reported that if they used these products, they usually administered 1 to 2 L per horse. The variable effects of administration of hyperimmune plasma or serum to horses with endotoxemia explain the diverse opinions of clinicians regarding the clinical efficacy of these solutions. These products probably have the best chance of having a beneficial effect if administered before or during the early stages of endotoxin absorption. If used, these products should be administered slowly initially and diluted in polyionic fluids to minimize any untoward effects. Anecdotal reports suggest a high rate of untoward reactions to hyperimmune plasma and serum in foals.

Polymyxin B is a cationic polypeptide antibiotic that has been shown to bind lipid A and to neutralize the actions of endotoxin in vitro. Polymyxin B is a broad-spectrum antibiotic, however, and because of a high potential for nephrotoxicity and neurotoxicity, it is not administered systemically to horses. Because polymyxin B exerts antiendotoxic activity at serum concentrations substantially lower than that required for its antimicrobial effects, it has been used in clinical trials for prevention and treatment of endotoxemia in human patients. In some studies, patients given polymyxin B have been shown to have improved immunologic function, decreased plasma endotoxin concentrations, and decreased mortality, compared with patients not given polymyxin B. There were also no adverse effects of polymyxin B observed. Pretreatment with 6000 IU/kg polymyxin B administered IV before 0.25 µg/kg *E. coli* LPS to 3- to 5-month-old foals caused significantly lower maximal TNF-α and IL-6 activities and significantly lower rectal temperature and respiratory rate, compared with foals given endotoxin but no polymyxin B. A study evaluating the effect of polymyxin B conjugated to dextran was performed to evaluate this combination for retaining the polymyxin B within the circulation (and thus preventing extravasation into tissues and toxic interaction with cell membranes, and decreasing the risk for development of adverse effects such as nephrotoxicity). A combination of a 5-mg/kg dose of polymyxin B and 6.6 g/kg of dextran was given to horses 15 minutes before experimental administration of endotoxin. Treatment with this combination prevented the tachycardia, tachypnea, fever, neutropenia, and the increased serum levels of TNF-α, IL-6, thromboxane B2, and the metabolite of PGI2 associated with endotoxin administration. This conjugated combination of polymyxin B and dextran is not currently available commercially.

Clinically, polymyxin B is administered to horses at a dosage of 1000 to 5000 IU/kg every 8 hours diluted in approximately 1 L of polyionic fluid. This therapy is typically continued for approximately 2 to 3 days, or until the signs of endotoxemia subside. Caution should be used in horses that are obviously dehydrated, hypovolemic, or azotemic, and until these abnormalities are corrected. Polymyxin B might have the best chance of providing protection to horses as a preventative measure, if it is possible to administer it before clinical signs develop; administration should probably be considered in horses predisposed to endotoxin absorption, such as horses with ischemic or inflammatory bowel disease.

Treatment of horses with a phospholipid emulsion at a dosage of 200 mg/kg was shown to delay and diminish the effects of low-dose (30 ng/kg, IV) endotoxin administration. Specifically, administration of phospholipid emulsion resulted in significantly decreased rectal temperature, heart rate, cardiac output, right atrial pressure and pulmonary artery pressure, and a higher total leukocyte count. There were also significant differences between treated and control horses for TNF-α, thromboxane B2, and the PGI2 metabolite.

### INTERFERING WITH SYNTHESIS OR ACTIVITY OF INFLAMMATORY MEDIATORS

Nonsteroidal anti-inflammatory drugs (NSAIDs) are the mainstay of treatment of horses with endotoxemia. Flunixin meglumine and phenylbutazone are the two most commonly used NSAIDs in these horses. In general, flunixin meglumine seems to be more effective at attenuating the cardiovascular effects of endotoxin, whereas phenylbutazone appears to offset the inhibitory effects of endotoxin on bowel motility. Administration of flunixin meglumine at 0.25 mg/kg IV every 8 hours has been shown to decrease eicosanoid concentrations, attenuate hemodynamic effects, and reduce lactic acidemia associated with experimental endotoxemia if administered before endotoxin infusion.

Although one study showed that phenylbutazone seems to be more effective for ameliorating the effects of endotoxin on bowel motility in horse, flunixin meglumine is also efficacious. Phenylbutazone can be administered at a dosage of 2.2 mg/kg IV every 12 hours to inhibit the effects of endotoxin on intestinal motility. Although we do not advocate it, some clinicians recommend the combined use of flunixin meglumine (0.25 mg/kg IV three times a day) and phenylbutazone (2.2 mg/kg IV twice a day) to minimize the effects of endotoxin on hemodynamics and intestinal motility *provided the horse is well hydrated*. In a study comparing ketoprofen and flunixin meglumine on the in vitro response of equine peripheral blood mononuclear cells to bacterial endotoxin, they both significantly decreased serum thromboxane B2, prostaglandin E2, 12-hydroxy-eicosatetraenoic acid, TNF-α, and tissue factor, suggesting that there does not appear to be any difference in
the effects of these two NSAIDs in inhibiting synthesis of inflammatory mediators associated with endotoxemia.\textsuperscript{50} It seems that most people continue to use flunixin meglumine to inhibit the effects of endotoxin on the cardiovascular system. Perhaps horses with azotemia or dehydration that may be more predisposed to the toxic effects of NSAIDs would be good candidates for administration of ketoprofen because of its less toxic effects on the gastrointestinal mucosa and renal papilla.\textsuperscript{51} Combination NSAID therapy must be administered with extreme caution because of the risk of potentiating the toxic effects on the intestinal mucosa and renal papilla; the drugs should be administered at the lowest possible dosages and for the shortest duration in well-hydrated horses. Because horses with illnesses commonly associated with endotoxemia develop or are predisposed to laminitis, NSAIDs are often the mainstay for prevention and treatment. Phenylbutazone appears to be more effective for musculoskeletal inflammatory conditions and pain, and it is commonly administered for prevention and treatment of laminitis.

Dimethyl sulfoxide (DMSO) is often administered to horses for its putative anti-inflammatory effects, which are related to its ability to scavenge oxygen-derived free radicals. Experimental evidence for the use of DMSO in horses with endotoxemia is lacking, but it has been shown to attenuate endothelial damage, hypoglycemia, hypotension, and lactic acidemia in endotoxic shock in other species.\textsuperscript{32} If used, DMSO should be administered at a dosage of 0.1 g/kg to 1 g/kg, and in solution at a concentration no greater than a 10% to 20%. Although it has been demonstrated to decrease ischemia/reperfusion injury of the intestinal mucosa in laboratory animals, no beneficial effects have been reported for ischemia/reperfusion injury in horses. Beneficial effects in laboratory animals have been demonstrated when DMSO is given as a pretreatment and at a dosage of 1 g/kg in these laboratory animals.\textsuperscript{31} Pretreatment is not practical in horses with colic, and the dosage that is often used in horses is much greater (100 mg to 1 g/kg). One study reported a potentially deleterious effect of DMSO on the large colon mucosa when administered after ischemia but before the reperfusion period.\textsuperscript{44}

Other antioxidants such as allopurinol, a competitive antagonist of xanthine oxidase, and 21-aminosteroids (which inhibit lipid peroxidation) have been shown to be protective against endotoxemia in other species. Allopurinol has been shown to exert some beneficial effect when administered to horses at 5 mg/kg 12 hours before endotoxin challenge.\textsuperscript{51} However, again, pretreatment is not particularly practical in the clinical situation,\textsuperscript{51} and thus allopurinol is not commonly used in horses.

Pentoxifylline (PTX) is a methylxanthine derivative that has been used for several years to treat intermittent claudication in people. Pentoxifylline is a rheologic agent that improves capillary blood flow by reducing blood viscosity and increased red blood cell deformability. More recently, PTX has been shown to exert pharmacologic effects in vivo and in vitro that may be beneficial in the treatment of endotoxemia, such as inhibition of TNF-α synthesis, decreased thromboxane B\textsubscript{2} concentrations and tissue thromboplastin activity, and increased PGI\textsubscript{2} concentrations. However, PTX has not been shown to attenuate the clinical signs of endotoxemia in human patients, and it does not exert any antipyretic or analgesic effects. Intravenous administration of 8 mg/kg of PTX 15 minutes before and 8 hours after IV administration of 30 mg/kg E. coli LPS resulted in a significantly greater PGI\textsubscript{2} concentration at 1.5 hours and lower plasminogen activator inhibitor activity at 12 hours, but TNF-α and IL-6 activities were not different from those in untreated horses.\textsuperscript{52} Administration of flunixin meglumine alone (1.1 mg/kg IV) 15 minutes before and again 8 hours after endotoxin administration resulted in a decrease in rectal temperature, total leukocyte count, and thromboxane B\textsubscript{2} concentration. Administration of a combination of flunixin meglumine (1.1 mg/kg IV) and PTX (8 mg/kg IV) did not cause an appreciable difference in the measured variables of this study, compared with administration of flunixin meglumine alone. Because this study did not assess survival as an outcome but rather only clinical signs and clinicopathologic variables, it is difficult to determine if administration of PTX would improve survival of horses with endotoxemia. Treatment with a combination of flunixin meglumine and PTX may be beneficial in horses and deserves further study.

Bolus administration of 7.5 mg/kg PTX immediately after IV administration of 20 mg/kg E. coli LPS and followed by an infusion of 3 mg/kg per hour over 3 hours resulted in significant differences in some measured variables compared with horses receiving only endotoxin.\textsuperscript{57} Although heart rate, rectal temperature, mean blood pressure, total leukocyte count, whole blood recalcification time, plasminogen activator inhibitor activity, TNF-α and IL-6 activities, and plasma thromboxane B\textsubscript{2} concentrations were significantly changed across time in horses receiving endotoxin and PTX and endotoxin alone, those receiving PTX had lower rectal temperature and respiratory rate and longer whole blood recalcification time than horses that did not receive PTX. Although it appeared that administration of PTX to horses as a bolus followed by a constant infusion caused significant changes in some measured variables, there appear to be minimal beneficial effects of PTX when administered IV using this regimen in this nonlethal equine model of endotoxemia.

Corticosteroids exert a number of beneficial effects that render them potentially useful in the treatment of endotoxemia, including inhibition of phospholipase A\textsubscript{2} and subsequent release of arachidonic acid from cell membranes, and a decreased synthesis of TNF-α, IL-1, and IL-6. However, there are also a number of potentially detrimental effects, including disruption of physiologic processes, inhibition of neutrophil migration, decreased bactericidal activity of neutrophils, increased susceptibility to bacterial and viral infections, and the apparent predisposition of horses to develop laminitis. Although one dose of corticosteroids probably does not put horses at great risk of complications, some clinicians are concerned about the potential for the development of laminitis. The dosage of dexamethasone required to inhibit TNF-α synthesis by equine peritoneal macrophages equates to a systemic dosage of approximately 3 mg/kg, which exceeds the currently recommended dosage that has been shown to have beneficial effects in experimental equine endotoxemia.\textsuperscript{23,53} However, many of the potentially beneficial effects of corticosteroids can be achieved with NSAIDs, and these effects do not outweigh the potential deleterious effects. Therefore, corticosteroids should not.
be used in the prevention or treatment of endotoxemia in horses.

INTERFERING WITH CELLULAR ACTIVATION
It has been shown that nontoxic LPS or nontoxic lipid-A substances can serve as endotoxin antagonists by competitively inhibiting binding to either LBP or cellular receptors. Because of these effects, numerous attempts to interfere with the interaction of cells and LPS and to halt intracellular signal pathways have been studied in laboratory animals and people.5,6 Of these substances, LPS and lipid A originating from the phototrophic bacterium Rhodobacter sphaeroides, and a synthetic substance with a structure similar to the R. sphaeroides LPS, are the most promising. However, unlike in other species, these substances act as potent stimulants of cytokine expression in equine cells.6 It is believed that this species difference may be associated with TLR4, which indicates that further studies are needed to clarify the potential role of these substances and their mechanism of action in horses.

A typical horse with signs of endotoxemia secondary to gastrointestinal tract disease would most likely be treated for the primary disease (e.g., mineral oil for grain overload, mucosal protectant for inflammatory bowel disease, surgical resection of ischemic-injured bowel), advanced medical and supportive care (e.g., IV crystalloids or colloids, antibiotics), NSAIDs (flunixin meglumine and/or phenylbutazone), neutralizing endotoxin (antiendotoxin serum, polymyxin B), or ancillary anti-inflammatory drugs (dimethyl sulfoxide, pentoxifylline).

Prevention
Maintenance and restoration of the intestinal mucosal barrier is an important factor in the prevention of endotoxemia and sepsis.4 Conditions favoring intestinal and colonic overgrowth favor development of sepsis and endotoxemia. Administration of antacids in critically ill patients may lead to proximal gut colonization by virulent bacteria because of increased gastric pH. Caution in administering antacids should be exercised, especially in critically ill neonates. Impaired intestinal motility associated with ileus and obstruction often leads to bacterial overgrowth. Therefore, prevention or rapid resolution of ileus should be a goal of management of these horses. Regarding prophylaxis, 77% of respondents to a survey indicated that they treat horses they consider at risk for developing endotoxemia even when the horses do not show clinical signs of endotoxemia. These prophylactic measures include administration of intravenous fluids (92%), low-dose flunixin meglumine (86%), antimicrobials (73%), hyperimmune antiendotoxoid plasma or serum (65%), high-dose (1.1 mg/kg) flunixin meglumine (50%), ketoprofen (50%), heparin (35%), aspirin (17%), and/or corticosteroids (7%).36

Prognosis
It is difficult to accurately determine the likelihood of survival of horses with endotoxemia, because this condition typically occurs subsequent to a variety of other diseases, each with its own severity, and because of the variation in the rapidity and amount of endotoxin gaining access to the circulation. However, the prognosis for horses with endotoxemia should be guarded because of the severity of the primary disease and the rapidly progressing pathophysiologic processes that are initiated when appreciable quantities of endotoxin gain access to the systemic circulation. Horses that develop endotoxemia secondary to gastrointestinal tract ischemia or inflammation (enteritis, colitis) are often so severely ill that they succumb to the effects of either the primary disease or the inflammatory cascade initiated by the interaction of endotoxin with the host's inflammatory cells. Early, aggressive treatment of the primary disease process along with a combination of the previously mentioned medications could improve the outcome in some horses, if the quantity of endotoxin reaching the systemic circulation is not overwhelming.

ON THE HORIZON
Future therapeutic regimens will probably be developed on the basis of temporal changes in gene expression that are identified through the use of modern molecular biology techniques. These treatments will most likely be geared toward modulation of the proinflammatory and anti-inflammatory cascades that are initiated by the systemic exposure of horses to endotoxin.

Monoclonal antibodies against specific mediators of the inflammatory process have been developed and administered to human patients to modulate the tissue damage in inflammatory diseases. For example, administration of monoclonal antibody directed against TNF-α (infliximab) has successfully suppressed tissue damage in patients with ulcerative colitis and Crohn's disease. New insights into cell-based and gene-based treatments against inflammatory disease in veterinary medicine are needed to apply these therapies to domestic animals.

Leukotriene inhibitors and antagonists have been used with success in a number of human diseases. Although these drugs have not yet been applied to veterinary medicine, research data have shown their effects to be promising. Medications currently available for human use include the following:

- Drugs (e.g., Zileuton and 5-aminosalicylic acid) that inhibit 5-lipoxygenase, thereby preventing metabolism of arachidonic acid to leukotrienes
- Drugs that block 5-lipoxygenase activating protein, preventing the action of 5-lipoxygenase
- Drugs that block the leukotriene-1 receptor, which is responsible for the bronchoconstrictor effects of leukotrienes. LTC4, LTD4, and LTE4 cause bronchoconstriction through effects on this receptor. Zafirlukast and montelukast are selective, competitive antagonists of this receptor that are approved for clinical use in people.

Because of species differences, mechanisms identified in humans and laboratory animals and subsequent treatments directed against these pathways or mediators cannot automatically be assumed (or extrapolated) to be effective, safe, and useful in horses. Controlled research studies and case-control clinical trials are needed to accurately determine the efficacy of new treatments in the clinical management of endotoxemia in horses.

CHAPTER 3

Fluids, Electrolytes, and Acid–Base Therapy
Joanne Hardy

Fluid administration for maintenance or replacement purposes is one of the mainstays of equine critical care, and the technology should be readily accessible in any equine hospital. The availability of commercial materials and fluids for use in large animals makes fluid administration easy and cost effective in most situations. This chapter reviews fluid and electrolyte balance, materials needed, and principles to follow when planning fluid administration.

NORMAL FLUID AND ELECTROLYTE BALANCE

Distribution of Fluids

Fluids in the body are distributed in two compartments: the intracellular fluid (ICF) volume and the extracellular fluid (ECF) volume. The ECF is composed of interstitial fluid, plasma, lymph, and transcellular fluids such as synovial, pleural, abdominal, and cerebrospinal fluids. The transcellular fluids do not normally contribute to significant fluid losses, but they may, in disease states such as pleuropneumonia or peritonitis, contribute significantly to volume deficits. For example, it is not unusual to drain 10 to 20 L of fluid from the pleural cavity of horses with severe pleuropneumonia. Additionally, the volume of gastrointestinal secretions in horses plays an important role in fluid distribution.

The normal volume of gastrointestinal secretion constitutes distributed across the ECF, a factor of 0.3 is used for equine peripheral blood monocytes to bacterial endotoxin, Can J Vet Res 1991;55:201-206.

NORMAL FLUID AND ELECTROLYTE BALANCE

Fluids in the body are distributed in two compartments: the intracellular fluid (ICF) volume and the extracellular fluid (ECF) volume. The ECF is composed of interstitial fluid, plasma, lymph, and transcellular fluids such as synovial, pleural, abdominal, and cerebrospinal fluids. The transcellular fluids do not normally contribute to significant fluid losses, but they may, in disease states such as pleuropneumonia or peritonitis, contribute significantly to volume deficits. For example, it is not unusual to drain 10 to 20 L of fluid from the pleural cavity of horses with severe pleuropneumonia. Additionally, the volume of gastrointestinal secretions in horses plays an important role in fluid distribution. The normal volume of gastrointestinal secretion in horses is approximately equivalent to the extracellular fluid volume, representing approximately 100 L every 24 hours in a 500-kg horse. Therefore, significant fluid sequestration and loss can occur with intestinal obstruction or colitis.

The volume of total body water (TBW) represents 60% of body weight in adults and up to 80% in neonates. The ECF volume represents 20% (in adults) to 40% (in neonates) of total body water, and the ICF volume, approximately 40%. Recent estimates of fluid distribution in horses report values of 0.67 L/kg (67%) for TBW, 0.21 L/kg (21%) for ECF, and 0.46 L/kg (46%) for ICF. In neonates, the ECF is approximately 40% of the TBW, and it decreases to approximately 30% by 24 weeks of age. For calculation purposes on substances distributed across the ECF, a factor of 0.3 is used for adults, and 0.4 for young animals. Blood volume in sedentary horses represents approximately 8% of body weight (see Chapter 4). In fit horses, this value can reach 14% of body weight. In neonates, blood volume represents 15% of body weight and decreases to adult values by 12 weeks of age.

Body fluids are not distributed equally throughout TBW. In plasma, sodium is the main cation, and bicarbonate and chloride are the main anions. Proteins contribute to the

Plasma, lymph, and transcellular fluids such as synovial, pleural, abdominal, and cerebrospinal fluids. The transcellular fluids do not normally contribute to significant fluid losses, but they may, in disease states such as pleuropneumonia or peritonitis, contribute significantly to volume deficits. For example, it is not unusual to drain 10 to 20 L of fluid from the pleural cavity of horses with severe pleuropneumonia. Additionally, the volume of gastrointestinal secretions in horses plays an important role in fluid distribution. The normal volume of gastrointestinal secretion in horses is approximately equivalent to the extracellular fluid volume, representing approximately 100 L every 24 hours in a 500-kg horse. Therefore, significant fluid sequestration and loss can occur with intestinal obstruction or colitis.

The volume of total body water (TBW) represents 60% of body weight in adults and up to 80% in neonates. The ECF volume represents 20% (in adults) to 40% (in neonates) of total body water, and the ICF volume, approximately 40%. Recent estimates of fluid distribution in horses report values of 0.67 L/kg (67%) for TBW, 0.21 L/kg (21%) for ECF, and 0.46 L/kg (46%) for ICF. In neonates, the ECF is approximately 40% of the TBW, and it decreases to approximately 30% by 24 weeks of age. For calculation purposes on substances distributed across the ECF, a factor of 0.3 is used for adults, and 0.4 for young animals. Blood volume in sedentary horses represents approximately 8% of body weight (see Chapter 4). In fit horses, this value can reach 14% of body weight. In neonates, blood volume represents 15% of body weight and decreases to adult values by 12 weeks of age.

Body fluids are not distributed equally throughout TBW. In plasma, sodium is the main cation, and bicarbonate and chloride are the main anions. Proteins contribute to the
negative charges, and they also provide oncotic pressure. Albumin or molecules of similar size are the main contributors to oncotic pressure. The interstitial fluid comprises about 75% of the ECF and it is composed mainly of sodium, bicarbonate, and chloride, but the concentration of protein there is lower. The slightly increased concentration of anions and decreased concentration of cations in interstitial fluids occurs because of the greater concentration of protein in plasma (according to the Gibbs-Donnan equilibrium). In clinical practice, this difference is small, so that the measured concentration of solutes in plasma is thought to reflect the concentration of solutes throughout the ECF. Table 3-1 lists normal plasma concentrations of electrolytes in adult horses. The composition of the intracellular fluid compartment is different: the important cations are potassium and magnesium, and the important anions are phosphates and proteins (Fig. 3-1).

Transfer of fluid between compartments is an important consideration when planning fluid administration. Some important concepts govern these mechanisms. Osmolality is defined as the concentration of osmotically active particles in solution per kilogram of solvent (mOsm/kg), whereas osmolarity is the number of particles of solute per liter of solvent (mOsm/L). In biologic fluids, the difference between the two concentrations is negligible, and the two terms are often used interchangeably. Normal plasma osmolality in adult horses ranges from 275 to 312 mOsm/kg, and it varies slightly between breeds. Lower values are reported for normal foals. The effective osmolality, or tonicity, is the osmotic pressure generated by the difference in osmolality between two compartments. Colloid oncotic pressure is the osmotic pressure generated by proteins, mainly albumin, and is measured using a colloid osmometer (Wescor, Logan, Utah).

Acid–Base Balance

The concentration of hydrogen ions, and therefore the pH, is closely regulated in the body to vary between 7.35 and 7.45. This narrow range is maintained by the presence of buffers within different body compartments; a buffer is a compound that can accept or donate protons to maintain the pH within a narrow range. In the body, bicarbonate is the primary buffer system of the extracellular fluid, whereas protein and inorganic and organic phosphates are the principal intracellular buffer system.

The importance of bicarbonate as a buffer in the ECF stems from the fact that it is an open system. The dissociation of carbonic acid is expressed by the law of mass action:

\[ \text{H}^+ + \text{HCO}_3^- \rightarrow \text{H}_2\text{CO}_3 \rightarrow \text{CO}_2 + \text{H}_2\text{O} \]

In the body, this system is open, and carbonic acid, in the presence of carbonic anhydrase, forms CO₂, which is eliminated entirely from the system by alveolar ventilation.

The relationship between pH, bicarbonate, and carbonic acid is expressed in the Henderson-Hasselback equation:

\[ \text{pH} = 6.1 + \log \left( \frac{\text{HCO}_3^-}{0.03 \times \text{PCO}_2} \right) \]

where \( \text{PCO}_2 \) is the partial pressure of carbon dioxide. This is the clinically relevant form of the equation, which shows that in body fluids, pH is a function of the ratio of \( \text{HCO}_3^- \) to \( \text{PCO}_2 \); this ratio is normally approximately 20:1.

The responses to acid or base alterations in the body all combine to normalize pH. For example, an acute increase in hydrogen ions from a fixed acid load is immediately buffered by bicarbonate and intracellular buffers. This is the acute physiochemical response. Alveolar ventilation is subsequently modified, and this is complete within hours to further minimize changes in pH by normalizing the ratio of \( \text{HCO}_3^- \) to \( \text{PCO}_2 \). Finally, renal responses result in regeneration of \( \text{HCO}_3^- \), resulting in a long-term response. The renal response begins within hours and is complete within 2 to 5 days. An acute increase in volatile CO₂, in contrast, cannot be buffered by HCO₃⁻; therefore, the hydrogen ions generated from the dissociation of carbonic acid must be buffered by intracellular buffers. Renal adaptation, characterized by increased HCO₃⁻ reabsorption and net acid secretion, takes 2 to 5 days to achieve maximal effectiveness.

**ACID–BASE DISORDERS**

**Terminology**

Acidosis and alkalosis refer to the processes that cause net accumulation of acid or alkali in the body, respectively. Acidemia and alkalemia refer to the pH of the ECF: in acidemia, the pH of the ECF is lower than normal, and in alkalemia the pH of the ECF is higher than normal. The distinction between these terms is important; for example a horse with chronic reactive airway disease may have a normal blood pH because of effective renal compensation, but in this setting the patient will have increased bicarbonate. This patient has alkalemia but does not have alkalemia.

**Primary Acid–Base Disorders**

There are four primary acid–base disorders: metabolic acidosis, metabolic alkalosis, respiratory acidosis, and respiratory alkalosis. The metabolic disorders refer to the net excess or deficit of nonvolatile or fixed acid, whereas the respiratory disturbances refer to a net deficit or excess of volatile acid (dissolved CO₂).

Metabolic acidosis is present when there is a decrease in HCO₃⁻ caused by either loss or buffering of nonvolatile acids. Common causes of metabolic acidosis in horses include accumulation of lactic acid as a result of poor perfusion, and HCO₃⁻ losses in the gastrointestinal tract resulting from diarrhea. Metabolic alkalosis is present when there is an increased concentration of HCO₃⁻. Metabolic alkalosis is commonly associated with a disproportionate loss of...
Respiratory acidosis is present when the partial pressure of carbon dioxide (PCO2) is increased in response to alveolar hypoventilation. Respiratory alkalosis is present when the PCO2 is decreased. Table 3-2 lists examples of primary acid–base disorders in horses.

For each primary acid–base disturbance, there is a secondary or adaptive response that involves the component opposite the primary disturbance, in an attempt to return the pH toward normal. The secondary response never restores the pH completely to normal. For metabolic disorders, the secondary or adaptive respiratory response begins immediately and is complete within hours. In respiratory disorders, the adaptive response begins with an acute, immediate titration by nonbicarbonate buffers that results in an initial change in plasma HCO3− concentration. This is followed by a chronic response mediated by the kidney that involves net acid secretion and bicarbonate resorption. This response begins within hours and takes 2 to 5 days to be complete. Table 3-3 lists expected adaptive responses to acid–base disorders. These expected responses vary slightly across species.13

### Mixed Acid–Base Disorders

When a primary disorder occurs with the expected secondary response, it is considered a simple acid–base disorder. A mixed disorder means that two separate primary disorders are present in the same patient. A mixed disorder is suspected when the adaptive response is lower or higher than the expected response from the primary disorder.

**Comments**

- There is a secondary increase in PCO2 to compensate for the primary disorder.
- There is a secondary decrease in P CO2 in an attempt at compensation.
- This is an acute disorder with increased bicarbonate of 1-2 mEq/L per 10 mm Hg increase in P CO2. Note that the BE is normal, indicating no metabolic disturbance.

MEASUREMENT AND INTERPRETATION OF BLOOD GASES

Measurement

For accurate blood gas analysis, appropriate sampling methods should be followed. Blood (arterial or venous) is collected anaerobically from the puncture site using a syringe that contains the appropriate anticoagulant for the analyzer, usually lithium heparin, taking care to not dilute the sample with excess heparin. Introduction of room air into the sample will falsely increase the partial pressure of oxygen and decrease the partial pressure of carbon dioxide. If a delay in analysis is anticipated, the blood should be placed on ice to decrease cell metabolism. Most blood gas analyzers perform their analysis at 37°C. At extremes of body temperature, a patient’s actual value may differ from expected according to the gas law: with increases in temperature, gas is less soluble and therefore its partial pressure in the solution increases; this will increase the PO2 and P CO2 of a solution. Similarly, with extreme hypothermia, gas is more soluble, resulting in decreases in PO2 and P CO2. Although available in many blood gas analyzers, temperature correction is usually not performed for several reasons: (1) the small changes in body temperature usually do not affect blood gas analyses significantly, (2) the patient’s temperature, if extreme, will usually be corrected shortly, and (3) there are no established normal values for extremes in body temperature.

Routine blood gas analyzers provide three measured values, pH, P CO2, and PO2, and three calculated values, total CO2 (TCO2), HCO3−, and base excess (BE). Measured values that are outside of physiologic ranges should be considered a malfunction of the analyzer.

- **pH** is the negative base 10 logarithm of hydrogen concentration and is a measured value.
- **P CO2 (mm Hg)** is the measured partial pressure of dissolved carbon dioxide in the sample. A venous sample will have a slightly higher (5 mm Hg) value than an arterial sample. An increase in P CO2 is termed hypercapnia or hypercarbia, and it usually reflects alveolar hypventilation. However, an increase in venous P CO2 may also reflect poor tissue perfusion.
- **PO2 (mm Hg)** is the measured partial pressure of dissolved oxygen in blood. This is different than oxygen content, which is the total concentration of oxygen carried by blood and includes the portion carried by hemoglobin.
- **TCO2 (mEq/L)** is the concentration of total CO2 in the sample, obtained by adding a strong acid to the sample and measuring the amount of CO2 produced, and it includes both dissolved CO2 and HCO3−. As HCO3− represents 95% of total CO2, this measurement is indirectly a measurement of HCO3− and it is 1 to 2 mEq/L higher than the concentration of HCO3−.
- **HCO3− (mEq/L)** is reported as actual bicarbonate, which is the calculated concentration of bicarbonate in the sample, and standard bicarbonate, which is the calculated concentration of HCO3− after the sample has been equilibrated to a P CO2 of 40 mm Hg.
- **BE (mEq/L)** is the amount of strong acid or base required to titrate 1 L of blood to a pH of 7.40 at 37°C with the P CO2 held constant at 40 mm Hg. Because the base excess is changed only by nonvolatile fixed acids, it is considered to reflect metabolic acid–base disturbances.

Normal values for the horse are presented in Table 3-1.

Interpretation

To interpret blood gases, a practiced method should be followed. First the pH is measured, and if it is outside the normal range, an acid–base disorder is present. The clinician examines next the HCO3− and P CO2 and determines if an abnormality is present that could explain the abnormal pH. An acidemia is caused by an increase in P CO2 or a decrease in HCO3−, whereas an alkalemia is caused by a decrease in P CO2 or an increase in HCO3−. Once the primary disorder has been characterized, the clinician determines whether a secondary response is present. The absence of a secondary response, or a change in the direction opposite the expected response, is an indication of a mixed disorder. The clinician then determines whether the acid–base disturbance is consistent with the patient’s history and clinical findings. Table 3-2 lists examples of simple acid–base disorders in horses.

Another important component of blood gas interpretation is the partial pressure of oxygen (PO2). The normal PO2 of arterial blood (PaO2) is approximately 5 times the fraction of inspired oxygen (Fi O2), or 80 to 100 mm Hg in room air at sea level (Fi O2, 21%). Hypoxemia refers to a decreased PaO2; common causes include a decreased Fi O2 (an example is a decreased barometric pressure associated with high altitude), hypoventilation, ventilation/perfusion mismatch, shunt, or diffusion impairment. The normal PO2 of venous blood is 40 mm Hg. A low mixed PVO2 (mixed refers to a sample collected centrally, ideally from the pulmonary artery) in the presence of normal PaO2 should alert to poor tissue perfusion.

Anion Gap

The anion gap (AG) is the difference between the sum of the commonly measured cations and the sum of the commonly measured anions in serum, calculated as follows:

\[ AG = (Na^+ + K^+) - (Cl^- + HCO_3^-) \]

The sum of cations always exceeds the sum of anions, and the difference is an attempt to estimate the concentration of unmeasured anions—for example, lactate. A normal anion gap of 10.4 ± 1.2 mEq/L has been reported in adult horses. Neonates have a slightly higher anion gap because of their increased levels of phosphates and globulins. In exercising horses, the anion gap is useful to estimate plasma lactate concentrations in the presence of relatively normal plasma protein concentrations. In horses with abdominal pain, the correlation between lactate concentration and the AG is excellent, but the presence of other strong ions results in a higher AG than would be expected from lactate measurement. The anion gap is considered a good prognostic indicator of survival in horses with abdominal disorders: a value of greater than 25 mEq/L is associated with a significantly lower survival rate.
Lactate
Measurement of lactate is now a routine part of the assessment of perfusion in equine patients, and it is available in most chemistry and point-of-care analyzers. Samples should be analyzed immediately to avoid in vitro lactate production by erythrocytes; alternatively, collection in fluoride-containing tubes, storage on ice, and plasma separation can help minimize this problem. Lactate is the end product of anaerobic glycolysis, and its concentration is another indicator of tissue perfusion and oxygen delivery; an increased blood lactate concentration is most often a result of tissue hypoxia. Although inadequate oxygen delivery to tissues as a result of hypovolemia, decreased oxygen content or impaired myocardial function (absolute hypoxia) is the most common cause of hyperlactatemia, hypermetabolic states or impaired oxygen utilization as a result of mitochondrial dysfunction (relative hypoxia) can also increase blood lactate concentration. Less commonly, increased lactate may result from impaired clearance because of hepatic dysfunction, thiamine deficiency, or increased catecholamine production. Normal blood lactate concentrations in resting adult horses are less than 2 mmol/L; concentrations higher than this in the adult are an indication of inadequate oxygen delivery. Neonates have higher blood lactate concentrations that decrease to adult values by 24 hours of age. Serial measurement of lactate is a useful tool to monitor the adequacy of fluid therapy (see Chapter 1).

Nontraditional Approach to Acid–Base Evaluation
In the traditional approach, the relationship between $P_{CO_2}$, $HCO_3^-$, and pH is explained by the Henderson-Hasselbalch equation and appears to stand alone as an explanation for acid–base derangements. This is still the approach most commonly used by clinicians, and it serves to initiate and target therapeutic intervention. However, what this approach fails to do is provide explanations for the influence of other electrolytes, weak acids, and plasma protein on acid–base balance.

The nontraditional approach (or Stewart’s approach) to acid–base balance is based on three physical laws: maintenance of electroneutrality, satisfaction of dissociation equilibrium for solutes that are incompletely dissociated, and conservation of mass. In this approach, independent variables are variables that can be changed externally; dependent variables are ones that change only when a change in independent variables occurs. Independent variables include the strong ion difference (SID), $P_{CO_2}$, and the total concentration of weak acids, or $A_{tot}$. The SID is the difference between the concentration of strong cations and the concentration of strong anions. The most important cation is sodium; chloride and other unmeasured anions make up the strong anions. Because many strong anions are not routinely measured, the normal strong ion difference accounts for the presence of these anions. An increase in SID indirectly indicates an accumulation of unmeasured anions.

The concentration of weak acids in plasma mostly derives from protein and phosphates. Bicarbonate is a dependent variable that changes in response to a change in independent variables. Hypoproteinemia (a decrease in weak acid) results in alkalosis (an increase in $HCO_3^-$); conversely, an increase in phosphates, as may occur in acute renal failure, causes an acidosis.

In Stewart’s approach, the primary disturbance is therefore defined as a change in one or more of the independent variables: [SID], $P_{CO_2}$, or $[A_{tot}]$. To calculate the contribution of these variables to an acid–base disturbance, determination of the total concentration of nonvolatile weak acids and the effective dissociation constant for weak acids is required, which is impractical in most clinical situations. A simplified version of Stewart’s approach, proposed and validated for equine plasma, allows the determination of $A_{tot}$ and $K_c$ and accurately predicts pH.

Another approach to Stewart’s concepts involves the characterization of four components of base excess: changes in free water reflected by changes in sodium, changes in chloride, changes in serum albumin concentration, and changes in unmeasured anions. This method has also been used successfully in horses to better characterize acid–base disorders. The example in Table 3-4 illustrates the contributions of protein, chloride, and unmeasured anions to acid–base balance, and it shows how the traditional approach to acid–base balance can sometimes fail to recognize abnormalities when complex disorders are present.

The preceding discussion emphasizes the complexity of interactions between solutes in body fluids, and the importance of recognizing the traditional approach to acid–base interpretation. Although the traditional approach provides a working method for identification of problems, it falls short.

Using the traditional approach to diagnosing acid–base disorders, the interpretation of blood gas analyses on this horse would indicate a metabolic alkalosis with no secondary or adaptive response ($P_{CO_2}$ is normal). Further examination reveals hypochloremia and hypoproteinemia, which are responsible for the alkalosis (as indicated by the calculation of their respective base excesses [$BE_{Cl}$ and $BE_{tp}$]). However, examination of the anion gap and calculation of the BE contributed by unmeasured anions ($BE_{ua}$) reveal an underlying acidosis that was masked by the hypoproteinemia and hypochloremia. Measurement of lactate would be indicated in this case to further characterize the disorder. Most likely, lactic acidosis is present as a result of poor perfusion (indicated by the marked increase in packed cell volume). $BE_{wa}$, BE contributed by free water.
in complex mixed acid–base disorders and does not provide a satisfactory explanation when electrolyte, colloidal, and unmeasured anion disorders coexist.

**DESIGNING A FLUID THERAPY REGIMEN**

**Volumes of Fluid to Administer**

Fluids can be administered for the purpose of maintenance or replacement. *Maintenance regimens* are often provided via the oral route in equine patients, and oral electrolyte formulations are available for this purpose (see Chapter 5). Intravenous maintenance fluids are lower in sodium and higher in calcium, potassium, and magnesium than replacement fluids. An appropriate maintenance fluid is 0.45% saline to which potassium, magnesium, and calcium were added.

More commonly, a *replacement fluid therapy regimen* is given to equine patients to replace fluids lost through dehydration and ongoing losses. When designing a replacement fluid therapy regimen, three questions must be answered:

1. What volume of fluid must be given?
2. What type of fluid will be given?
3. What will be the rate of administration?

Furthermore, the volume of fluids given must equal the *maintenance requirements* plus the volume needed to *correct hypovolemia* plus that needed to compensate for *ongoing losses*.

**Maintenance**

In adult horses, maintenance fluid requirements have been estimated at 60 mL/kg per day. This figure probably overestimates the actual needs of a resting, fasted animal in a normothermic environment, but it appears to be safe in most situations. In horses with renal failure, when elimination of excess fluids is difficult, monitoring of body weight and central venous pressures is indicated to help avoid fluid overload. If weight gain, edema, or increased central venous pressures are noted, the fluid rate should be decreased.

**Dehydration**

*Dehydration* is the general term used to indicate loss of total body water; *hypovolemia* is a form of dehydration resulting from loss of effective circulating volume. This distinction is important; for example, when the lack of water intake is prolonged, heart rate and parameters of perfusion remain within normal limits, as fluid shifts from the intracellular space to maintain normal circulating volume. In this case, replenishment of intracellular fluid volume should be performed relatively slowly, to allow time for fluid shifts to occur. In contrast, acute intestinal obstruction results in loss of circulating blood volume manifested by altered cardiovascular parameters such as increased heart rate, poor perfusion, and decreased pulse quality. Rapid restitution of effective circulating blood volume is important in this situation. Parameters that may be used for estimation of dehydration include serial body weights, heart rate, mucous membrane color, capillary refill time, skin elasticity (skin tenting), palpation of extremities, and urine output. Useful laboratory parameters include packed cell volume (PCV), total protein, creatinine and lactate concentrations, and urine specific gravity. Table 3-5 lists parameters useful for estimating hypovolemia (loss of effective circulating volume) in the horse.

Once an estimate of hypovolemia has been obtained, the amount of fluids to give is calculated as follows:

\[
\text{Correction of hypovolemia} = \text{estimate of loss} (%) \times \frac{\text{body weight (kg)}}{}.
\]

**Ongoing Losses**

Ongoing losses can sometimes be measured and recorded—for example, when nasogastric reflux is present—but usually they must be estimated. Therefore, patient monitoring is used to determine if the calculated fluid volume is meeting the ongoing losses. Monitoring, which may include serial measurements of cardiovascular parameters, PCV and total protein, lactate concentration, and blood gas analyses, is done at least twice a day when patients are on intravenous fluids, but it should be done more frequently (every 2, 4, or 6 hours) depending on the severity of cardiovascular compromise. Creatinine concentration should also be monitored at least once daily when initially elevated, to ensure adequate return to normal. Additional means of monitoring adequate fluid delivery include measurement of central venous pressure, arterial blood pressure, and urine output.

**Type of Fluid**

The type of fluid chosen depends on the evaluation of the chemistry profile and on the disease state. The first step is to choose a baseline fluid (saline or balanced electrolyte

These parameters are useful to estimate the degree of hypovolemia in adult horses, assuming a normal packed cell volume (PCV) of 35% and total protein (TP) of 6.5 g/dL.
solution), and the second is to decide which additives to add to the baseline fluid. The choice of additives depends on the specific deficits or excesses, such as hypo- or hypernatremia, hypo- or hyperkalemia, hypo- or hypercalcemia, hypo- or hypermagnesemia, hypoglycemia, or acid–base disorders.

The two categories of crystalloids commonly used for fluid replacement are 0.09% saline and balanced electrolyte solutions (BESs). Table 3-6 lists the compositions of various commercially available fluids. In general, BESs are chosen when serum electrolytes are close to normal. The BES provides a bicarbonate precursor, which is either lactate, or acetate plus gluconate. Lactate requires hepatic metabolism for conversion to bicarbonate, whereas acetate and gluconate are metabolized by other tissues. All BESs contain some potassium. As noted in Table 3-6, calcium or magnesium is present in different types of BES. Saline (0.09%) is higher in sodium and much higher in chloride than serum concentrations and is used when [Na+] is lower than 125 mEq/L. Saline is also used in disease processes associated with high [K+], such as hyperkalemic periodic paralysis or renal failure, where a potassium-free solution is preferred. In cases of long-term maintenance fluid therapy (greater than 4 to 5 days), if the oral route is not available, half-strength basic fluids, to which potassium, calcium, and magnesium are added, should be considered. Long-term fluid therapy solely with a BES will result in hypernatremia, hypokalemia, hypomagnesemia, and hypocalcemia.

In horses, routine fluid replacement also includes calcium, potassium, and magnesium supplementation, particularly when there is no oral intake because of gastrointestinal disease. Low concentrations of serum ionized calcium (iCa) and magnesium (iMg) are more prevalent in horses with surgical gastrointestinal disease, particularly in those with small intestinal or large and small colon nonstrangulating infarction or strangulation and in horses with postoperative ileus. Horses with enterocolitis also have low iCa and iMg and a decreased fractional clearance of calcium. Total magnesium and calcium concentrations are less reliable for identification of calcium and magnesium status—it is preferable to determine ionized concentrations. Measurement of total calcium can be misleading if total protein is low (ionized calcium may still be normal) or if the horse is alkalotic (total calcium may be normal, with a low ionized fraction). Recently, fractional excretion of magnesium has been suggested as a diagnostic tool for assessment of magnesium status in horses. Based on this information, supplemental calcium and magnesium appears beneficial for fluid therapy in horses.

Administration of 50 to 100 mL of 23% calcium gluconate in every 5 L of fluid is usually sufficient to maintain normocalcemia. In the presence of severe hypocalcemia (iCa less than 4.0 mg/dL), administration of 500 mL of calcium gluconate in 5 L of BES is indicated. Hypocalcemia that is refractory to calcium therapy may indicate hypomagnesemia, and concurrent magnesium replacement is required. The maintenance requirement of magnesium in horses is estimated at 13 mg/kg per day of elemental Mg, which is provided by 31 mg/kg per day of MgO, 64 mg/kg per day of MgCO3, or 93 mg/kg per day of MgSO4. In critically ill patients, the requirement may be increased, as indicated by the high prevalence of hypomagnesemia in hospitalized patients. When considering magnesium supplementation, the concentration of elemental magnesium in the compound should be considered. Some crystalloid fluids such as Plasma-Lyte A and Normosol-R contain 3 mEq/L of elemental Mg. This amount may be insufficient to account for the increased losses in sick horses. Administration of 150 mg/kg per day of MgSO4 (0.3 mL/kg of a 50% solution), equivalent to 14.5 mg/kg per day or 1.22 mEq/kg per day of elemental magnesium, administered in saline, dextrose, or polyionic fluids, would provide the daily requirement for the horse.

Hypokalemia may develop because of lack of intake, diuresis, and gastrointestinal loss through diarrhea. Horses with a metabolic acidosis can become hyperkalemic, and potassium excretion can occur after correction of the acidemia. Measurement of serum potassium as an estimate of total body potassium can be misleading, because most of the potassium ion is intracellular. Routine potassium supplementation is indicated if lack of intake and fluid therapy are continued for more than 24 hours. To avoid any complication, it is recommended that animals not receive more potassium than 0.5 mEq/kg per hour. Most horses will benefit from the addition of 12 mEq of potassium chloride per liter of fluids (80 mEq per 5-L bag).

*Manufactured by Ceva Laboratories, 10560 Barkley Street, Overland Park, KS 66121.
Bicarbonate supplementation may also be required in horses with metabolic acidosis. Because the most common cause of nonrespiratory acidosis is lactic acidemia resulting from poor perfusion, providing fluid replacement should be the first and principal means of correcting this problem. The following are rules of thumb for bicarbonate supplementation in acute metabolic acidosis:

- The horse should have normal respiratory function. If it is unable to exhale the generated CO₂ because of a respiratory problem, worsening of the acidosis will result.
- The blood pH should be less than 7.2. In acute acidosis associated with dehydration, fluid replacement will result in restoration of urine output, and renal compensation will follow and usually be complete if the pH is greater than 7.2.
- Half of the calculated amount should be administered rapidly, followed by the rest over 12 to 24 hours.
- IV bicarbonate should not be given with calcium-containing solutions.

In chronic metabolic acidosis, particularly when there are ongoing losses of bicarbonate (e.g., when there is diarrhea), the full calculated amount is usually required, partially because the bicarbonate loss is distributed over all fluid compartments, not just the extracellular fluid. Oral is a good means of dealing with ongoing losses in horses with diarrhea. Bicarbonate can be given orally as a powder (1 g NaHCO₃ = 12 mEq HCO₃⁻).

Administration of dextrose is indicated for the treatment of hypotonic dehydration, for animals susceptible to or diagnosed with hyperlipemia (miniature horses and donkeys, adult horses with azotemia), and for pregnant mares as a source of energy for the fetoplacental unit.30,31 As glucose is metabolized rapidly, administration of dextrose in water results in the administration of free water, which is useful for the correction of intracellular dehydration. As a source of energy, 5% dextrose can be administered at a rate of 1 to 2 mg/kg per minute.

Administration of colloids is indicated when the total protein concentration is less than 4 mg/dL, the albumin concentration is less than 2.0 mg/dL, or the colloidal oncotic pressure is less than 12 mm Hg. Plasma and hetastarch are commonly used colloids in horses (see Chapter 1). Plasma administration is indicated when administration of other plasma products such as coagulation factors or antithrombin III is desired in addition to administration of colloids. The amount of plasma to be administered can be calculated as follows:

\[
\text{Plasma to be administered} = \frac{(\text{TP}_{\text{des}} - \text{TP}_{\text{pt}}) \times 0.5 \times \text{BW (kg)}}{\text{TP}_{\text{don}}},
\]

where TP_{des} is the desired protein concentration, TP_{pt} is the total protein concentration of the patient, and TP_{don} is the total protein concentration of the donor plasma. If the goal of colloid therapy is to restore oncotic pressure, then synthetic colloids can be used. Before the advent of hetastarch, dextran was commonly used, but its administration was associated with more anaphylactoid reactions, and because of its lower molecular weight average, it had a shorter duration of effect.5 Hetastarch is preferred and is used at a dosage of 10 mL/kg. Higher dosages (20 mL/kg) were associated with increased coagulation times caused by a decrease in von Willebrand factor antigen (vWF:Ag) activity and factor VIII coagulant (FVIII:C), and should probably not be used in sick animals with increased susceptibility to coagulopathies. Hetastarch registers at a lower value than protein on a refractometer and can therefore decrease the value of the total protein concentration that is measured. To accurately monitor hetastarch therapy, use of a colloid osmometer is indicated.

Administration of blood or blood substitutes (see Chapter 4) is indicated when loss of oxygen-carrying capacity has occurred through red blood cell loss. Ideally, fresh whole blood collected in a plastic container (to preserve platelet function) from a donor that is negative for the red blood cell antigens A and Q and with an appropriate anticoagulant should be given. Commercially available kits (Dynavet, Veterinary Dynamics, Templeton, Calif.) consist of 2-L collection bags, collection and administration sets, and anticoagulant. Blood stored for greater than 10 days has a decreased concentration of 2,3-diphosphoglycerate, resulting in decreased oxygen release into tissues, increased red blood cell fragility, and increased potassium concentration. For prolonged storage of equine blood, the use of citrate-phosphate-dextrose with supplemental adenine has recently been recommended.32 In cases of chronic blood loss, the amount of blood required can be calculated as follows:

\[
\text{Amount required (L)} = \frac{\left[\text{PCV}_{\text{des}} - \text{PCV}_{\text{pt}}\right] \times 0.8 \times \text{BW (kg)}}{\text{PCV}_{\text{don}}},
\]

where PCV_{des} is the target packed cell volume, PCV_{pt} is the patient's packed cell volume, PCV_{don} is the PCV of the donor, and BW is body weight. When the blood loss is acute, the packed cell volume does not reflect the amount of blood lost for up to 24 hours. If blood loss is considered severe, 10 to 20 mL/kg of whole blood can be administered. When a large volume of anticoagulated whole blood is administered, the patient should be monitored for anaphylactic reaction and hypocalcemia.

Oxyglobin, a hemoglobin-based oxygen carrier, is a glutaraldehyde-polymerized bovine hemoglobin solution that has been administered safely to horses for restoration of oxygen-carrying capacity.33-35 After administration, volume expansion also occurs because of the colloidal nature of the solution. In one study performed in ponies with experimentally-induced normovolemic anemia, administration of 15 mL/kg given at the rate of 10 mL/kg per hour improved hemodynamics and oxygen transport parameters without adverse renal or coagulation effects; however, one pony suffered an anaphylactoid reaction during infusion.17 The half-life of Oxyglobin is relatively short; therefore, the patient should be monitored if the need for another transfusion may arise.32 Expense may limit its use in adult horses.

**Rate of Administration**

In severe shock, a shock dose of fluids (60 to 90 mL/kg) should be given in the first hour. This can be done only with pressurized bags or a pump. In other situations, the rate of administration is calculated on the basis of 24-hour requirements and estimated as a volume per hour. It is
important to keep a tally of the fluids given to ensure that the correct amount is reached.

Oral Fluids
Although the oral route of fluid administration has been neglected with the advent of commercially available intravenous fluids for horses, interest is being revived, particularly in the treatment of impaction colic. Oral fluids should be considered when the gastrointestinal tract is functional and maintenance requirements are needed—for example, in a dysphagic horse and as a principal means of treatment of impaction colic. Enteral fluid therapy may complement and even supplement intravenous fluids. Advantages of enteral fluid therapy include administration of fluid directly into the gastrointestinal tract, stimulation of colonic motility through the gastrocolic reflex, decreased expense, and decreased need for precise adjustment of fluid composition. Enteral fluids may be administered by intermittent nasogastric intubation, or by placement of an indwelling feeding tube (18-French equine enteral feeding tube, Mila International, Florence, Ky.), allowing continuous fluid administration.

An isotonic electrolyte solution can be made by mixing 5.27 g of NaCl, 0.37 g of KCl, and 3.78 g of NaHCO₃ per liter of tap water. This solution results in the following electrolyte concentrations: 135 mEq/L of Na⁺, 95 mEq/L of Cl⁻, 5 mEq/L of K⁺, and 45 mEq/L of HCO₃⁻, with a measured osmolality of approximately 255 mOsm/L, representing a balanced, slightly hypotonic electrolyte solution compared with plasma. Plasma electrolyte concentrations remain within normal range with this solution compared with the marked hypernatremia and hyperchloremia observed when 0.9% saline is administered enterally.

Although normal horses can tolerate up to 10 L hourly, it is usually not possible to administer more than 5 L every 2 hours to horses with impactions, as they start to reflux when more fluid is given. Thus, intermittent intubation allows administration of approximately 60 L of fluids per day. When continuous enteral fluids are given, a greater rate of administration is tolerated, and horses can be given between 4 and 10 L/h. At the higher rate of 10 L/h, mild signs of abdominal pain were observed in normal horses, and in horses with large colon impaction, a rate of 5 L/h is better tolerated. In one study, right dorsal colon ingesta hydration was significantly increased after enteral fluid therapy compared with intravenous fluid therapy combined with enteral administration of magnesium sulfate.

FLUIDS USED FOR RESUSCITATION

Isotonic Crystalloids
Isotonic crystalloid fluids are administered intravenously and immediately reconstitute the circulating volume. However, because they are crystalloids, they are distributed to the entire extracellular compartment within a matter of minutes. Because the ECF compartment is approximately 3 times the volume of blood, 3 times as much isotonic crystalloid must be administered to gain the desired amount of circulating volume expansion. As an example, if blood loss is estimated at 30% of blood volume, representing 12 L for a 500-kg horse, then 36 L of a crystalloid fluid is required. An estimated shock dose for crystalloids is therefore 60 to 90 mL/kg per hour.

Hypertonic Crystalloids (7.2% NaCl)
Hypertonic crystalloid fluids (7.2% NaCl) have approximately 8 times the tonicity of plasma and ECF (composition: Na⁺, 1200 mOsm/L, Cl⁻, 1200 mOsm/L). Their immediate effect is to expand the vascular volume by redistribution of fluid from the interstitial and intracellular spaces. Each liter of hypertonic saline will expand blood volume by approximately 4.5 L. However, this effect is short-lived. As the electrolytes redistribute across the ECF, fluids shift back and the patient once again becomes hypovolemic. Because the principal effect of hypertonic saline is fluid redistribution, there still exists a total body deficit, which must be replaced. The duration of effect of hypertonic solutions is directly proportional to the distribution constant, which is the indexed cardiac output. In horses, the duration of effect is estimated at approximately 45 minutes. The recommended dosage is 4 mL/kg, administered as rapidly as possible. Because of its short duration of effect, hypertonic saline administration must be followed with isotonic volume replacement at shock doses (see earlier).

COLLOIDS
Colloids are fluids that contain a molecule that can exert oncotic pressure. These molecules do redistribute to the ECF, but at a much slower rate than crystalloids, so that the duration of effect is prolonged compared with crystalloids. Hetastarch, because of its long duration of effect, is the most commonly used fluid for volume expansion in horses. Each liter of administered colloid will further expand the circulating blood volume by approximately 1 L, resulting in a total fluid expansion of 2 L. If hetastarch is used at a dosage of 10 mL/kg, the resulting increased colloid pressure will be significant for up to 120 hours in horses. For shock therapy, the combination of hypertonic saline at 4 mL/kg and hetastarch at 4 mL/kg will prolong the resuscitation efforts and be more beneficial than either fluid alone.

MATERIALS FOR FLUID ADMINISTRATION

Intravenous Catheters
Intravenous catheters are available in varying materials, construct, length, and diameter (Tables 3-7 and 3-8). In choosing a catheter, the desired fluid rate, the fluid viscosity, the length of time the catheter will remain in the vein, the severity of the systemic illness, and the size of the animal should be considered. The rate of fluid flow is proportional to the diameter of the catheter and inversely proportional to the length of the catheter and the viscosity of the fluid. Standard adult horse catheter sizes are usually 14 ga in diameter and 13 cm (5.25 inches) in length. For more rapid administration rates (shock), a 12 ga or 10 ga should be used. Plasma and blood products flow more slowly because of their increased viscosity, so if volume replacement is also needed, administration of these fluids can be combined with a balanced electrolyte solution. Teflon catheters should be changed every 3 days, whereas polyurethane catheters may remain in the vein for up to 2 weeks. Horses that are
very ill (bacteremic, septicemic, endotoxic) are more likely to encounter catheter problems and benefit from polyurethane or silicone catheters.

The catheter construction needs also to be considered (see Table 3-8). Through-the-needle catheters are most common for standard-size adult horses. An over-the-wire catheter is best for foals and miniature horses, or when the lateral thoracic vein is catheterized. Short and long extension sets are available, as well as small- and large-bore diameters. It is best to use an extension that screws into the hub of the catheter, to avoid dislodgement. In horses with low central venous pressures, disconnection of the line may result in significant aspiration of air and cardiovascular collapse. Double extensions are also available when other medications need to be administered with the fluids.

Catheter Maintenance

In adults, catheters are usually not covered with a bandage but rather are sutured in place, so that any problem is quickly identified. Bandages may need to be applied in foals if they are tampering with the catheter. A triple antibiotic ointment may be applied at the insertion site on the skin to decrease the risk of infection. Catheters should be flushed with heparinized saline (10 IU/mL) four times a day if they are not used for fluid administration. When administering a medication, the injection cap should be wiped with alcohol prior to insertion of the needle. The injection cap should be changed daily. All infected catheters should be cultured for identification of the causative organism and for possible nosocomial infection.

Coil Sets and Administration Sets

Coil sets are used for in-stall fluid administration. They are essential as they allow the horse to move around, lie down, and eat without restraint. An overhead pulley system with a rotating hook prevents fluid lines from getting tangled.

Administration sets are used for short-term fluid or drug administration and are available at 10 drops/ml and 60 drops/ml. When using a calibrated fluid pump, care should be taken to use the appropriate set calibrated for the brand of pump. Long coiled extension sets may then be used to connect fluids to the horse. Foal coil sets (18 French equine enteral feeding tube, Mila International, Florence, Ky.) are also available that deliver 15 drops/mL.

Pump Delivery

Calibrated pumps are available that allow delivery at various rates. These pumps have alarms that signal air in the line, empty fluid bags, or catheter problems. The maximal fluid rate these pumps can deliver is 999 mL/hour, which is usually not rapid enough to provide fluid replacement in adult horses, but they are useful for foals or for constant rate infusions. For large-volume fluid delivery, peristaltic pumps are available that can deliver up to 40 L/h. These must be under constant supervision when in use, as the pumps will continue to run even if fluids run out. Large-bore catheters should be used to avoid trauma from the jet effect on the endothelium of the vein.

Sites for Intravenous Catheterization in Horses

Common sites for insertion of intravenous catheters in horses include the jugular, lateral thoracic, cephalic, and saphenous veins. The lateral thoracic vein makes an acute angle with the internal jugular just at the level of the clavicular head of the sternohyoideus muscle.
angle as it enters the chest at the fifth intercostal space. Therefore, a short (7.5-cm) or an over-the-needle catheter is best used when catheterizing this vein. When catheters are placed in any location other than the jugular vein, more frequent flushings (every 4 hours) are required, as these catheters tend to clot more easily. Leg catheters are usually bandaged, because they are more prone to dislodgment than jugular catheters.

**Oral Feeding Tubes**

Oral fluid administration offers a good alternative to intravenous fluid therapy in animals that require maintenance fluids because of an inability to swallow, or in horses with impaction colic. Enteral nutrition (see Chapter 6) can also be administered for complete or partial enteral nutrition in foals and adults. Commercially available feeding tubes* for foals, weanlings, and adults enable fluid or liquid diet supplementation while allowing the horse to continue to nurse or eat.

CHAPTER 4

Hemostasis, Surgical Bleeding, and Transfusion
Barbara L. Dallap Schaer

PHYSIOLOGY OF HEMOSTASIS

Physiologic hemostasis is critical in preoperative, intraoperative, and postoperative surgical management. A complete understanding of the physiology of hemostasis, the ability to identify patients at risk for development of hemostatic dysfunction, and knowledge of appropriate and timely therapeutic intervention are essential for any successful surgical outcome. Hemostasis is a balancing act between the ability to rapidly form clots to prevent excessive hemorrhage (coagulation) and the necessary clot dissolution to restore nutrient blood flow to vital tissues and end organs (fibrinolysis). Trauma (surgical or other), endotoxemia, sepsis, and neoplasia are just a few of the possible inciting events that disrupt the delicate balance of physiologic hemostasis. Blood vessels, platelets, coagulation factors, anticoagulants, and fibrinolysis are the pillars of hemostasis and will be discussed individually.

Blood Vessels and the Role of the Vascular Endothelium

Intact blood vessels resist clot formation through a number of mechanisms. The vascular endothelium is responsible for maintaining a nonthrombogenic environment to provide passage for the flow of nutrient blood and the thrombogenic platelet. Vasodilation helps to resist clot or fibrin formation by promoting low-turbulence blood flow in the absence of vascular damage or injury.

The metabolic activities of the vascular endothelium play a large role in maintaining a nonthrombogenic environment. Through the action of prostacyclin synthetase within the endothelial cell, arachidonic acid is converted to prostacyclin, a potent inhibitor of platelet aggregation.1 Thrombomodulin is also produced by the endothelial cell, which serves to inhibit thrombin and promote the activity of protein C (anticoagulant).2 The activity of antithrombin, the most potent natural anticoagulant, is enhanced by the production of specific glycosaminoglycans produced within the endothelium.3

These mechanisms are kept in careful balance with the procoagulant properties of the vascular endothelium, which are activated when there is vascular disruption or denuding of the endothelium. The immediate response of the blood vessel to injury is vasoconstriction. This is mediated through local signaling from damaged endothelial cells, perhaps through interruption of the release of endothelial-derived relaxation factors. Prompt vasoconstriction prevents unnecessary blood loss and promotes rapid fibrin formation. Alternatively, inappropriate or excessive activation of these procoagulant properties may play a role in the hemodynamic instability and end-organ failure often observed in severe endotoxemia or sepsis.4

The subendothelium of the blood vessels provides the primary surface on which passing platelets and coagulation factors are activated, and it is traditionally thought to be the primary contributor of the vascular endothelium for the promotion of clot formation. A number of coagulation-promoting proteins are produced, but they are not necessarily exposed on the endothelial surface until activated by inflammatory mediators.5 Von Willebrand factor (vWF), factor V, platelet activating factor (PAF), and tissue factor are all procoagulant proteins produced in the endothelial cell. It has been proposed that in the presence of inflammatory mediators, the endothelial cell may undergo a monocyte-like phenotype change, resulting in a reduction in the production of endothelium-derived relaxation factors and other antithrombogenic properties.5 The effect of endotoxin on vessel dysfunction and activation of a procoagulant state has been reported (see Chapter 2).6,7 A recent study revealed that vascular endothelial damage was the primary cause of multiorgan failure in thrombocytopenic patients, and the damage was most likely linked to the effects of specific inflammatory mediators.8 Because of the vital role blood vessels and vascular endothelium play in the maintenance of hemostasis, therapeutics aimed at the prevention of endothelial damage in the presence of inflammatory mediators are likely to be a focus of future critical care research. Given the extreme sensitivity of the horse to endotoxin, control of vascular endothelial damage in the horse undergoing surgical treatment of gastrointestinal disease may be quite relevant.
Physiologic hemostasis is critical in preoperative, intraoperative, and postoperative surgical management. A complete understanding of the physiology of hemostasis, the ability to identify patients at risk for development of hemostatic dysfunction, and knowledge of appropriate and timely therapeutic intervention are essential for any successful surgical outcome. Hemostasis is a balancing act between the ability to rapidly form clots to prevent excessive hemorrhage (coagulation), and the necessary clot dissolution to restore nutrient blood flow to vital tissues and end organs (fibrinolysis). Trauma (surgical or other), endotoxemia, sepsis, and neoplasia are just a few of the possible inciting events that disrupt the delicate balance of physiologic hemostasis. Blood vessels, platelets, coagulation factors, anticoagulants, and fibrinolysis are the pillars of hemostasis and will be discussed individually.

**Blood Vessels and the Role of the Vascular Endothelium**

Intact blood vessels resist clot formation through a number of mechanisms. The vascular endothelium is responsible for maintaining a nonthrombogenic environment to provide passage for the flow of nutrient blood and the thrombogenic platelet. Vasodilation helps to resist clot or fibrin formation by promoting low-turbulence blood flow in the absence of vascular damage or injury.

The metabolic activities of the vascular endothelium play a large role in maintaining a nonthrombogenic environment. Through the action of prostacyclin synthetase within the endothelial cell, arachidonic acid is converted to prostacyclin, a potent inhibitor of platelet aggregation. Thrombomodulin is also produced by the endothelial cell, which serves to inhibit thrombin and promote the activity of protein C (anticoagulant). The activity of antithrombin, the most potent natural anticoagulant, is enhanced by the production of specific glycosaminoglycans produced within the endothelium.

These mechanisms are kept in careful balance with the procoagulant properties of the vascular endothelium, which are activated when there is vascular disruption or denuding of the endothelium. The immediate response of the blood vessel to injury is vasoconstriction. This is mediated through local signaling from damaged endothelial cells, perhaps through interruption of the release of endothelial-derived relaxation factors. Prompt vasoconstriction prevents unnecessary blood loss and promotes rapid fibrin formation. Alternatively, inappropriate or excessive activation of these procoagulant properties may play a role in the hematologic instability and end-organ failure often observed in severe endotoxemia or sepsis.

The subendothelium of the blood vessels provides the primary surface on which passing platelets and coagulation factors are activated, and it is traditionally thought to be the primary contributor of the vascular endothelium for the promotion of clot formation. A number of coagulation-promoting proteins are produced, but they are not necessarily exposed on the endothelial surface until activated by inflammatory mediators. Von Willebrand factor (vWF), factor V, platelet activating factor (PAF), and tissue factor are all procoagulant proteins produced in the endothelial cell. It has been proposed that in the presence of inflammatory mediators, the endothelial cell may undergo a monocyte-like phenotype change, resulting in a reduction in the production of endothelium-derived relaxation factors and other antithrombogenic properties. The effect of endotoxin on vessel dysfunction and activation of a procoagulant state has been reported (see Chapter 2). A recent study revealed that vascular endothelial damage was the primary cause of multiorgan failure in thrombocytopenic patients, and the damage was most likely linked to the effects of specific inflammatory mediators. Because of the vital role blood vessels and vascular endothelium play in the maintenance of hemostasis, therapeutics aimed at the prevention of endothelial damage in the presence of inflammatory mediators are likely to be a focus of future critical care research. Given the extreme sensitivity of the horse to endotoxin, control of vascular endothelial damage in the horse undergoing surgical treatment of gastrointestinal disease may be quite relevant.
Platelets

In many ways, platelets are the workhorse of a balanced hemostatic system. The interaction of the activated platelet with exposed subendothelium of blood vessels is the basis of primary hemostasis. Platelets also play a key role in secondary hemostasis: once activated, they undergo conformational changes exposing binding sites (platelet factor 3) for specific coagulation factors. Additionally, even though platelets have a relatively simple anuclear structure, they release ADP and a number of regulatory proteins from complex storage granules that are critical in initiating fibrin formation.

Platelet Physiology and Anatomy

Platelets originate from a process of megakaryocytopenesis, which produces a membrane-encased cytoplasmic fragment of the original megakaryocyte. Megakaryocytes originate primarily in bone marrow. The specific signals responsible for the upregulation of platelet production are not entirely defined, but it is likely that specific hematopoietic growth factors are necessary for platelet growth and development.\(^9\)

These anucleate, disc-shaped cells do not have the ability to synthesize proteins, but they are capable of specific metabolic activities such as arachidonate and phospholipid metabolism.\(^1\) The human platelet is approximately 2 to 3 \(\mu\)m in its unactivated state, but its complex cytoskeleton infrastructure and associated microtubules allow it to change shape dramatically once activated, exposing critical binding sites for coagulation factors and cofactors. The platelet plasma membrane is also quite sophisticated, consisting of an open canalicular system that facilitates secretion of essential platelet products.

Dense granules, \(\alpha\)-granules, and lysosomes store the majority of platelet proteins needed for the initiation of coagulation. Dense granules store calcium, a common cofactor in platelet–phospholipid interactions, as well as ADP, ATP, and serotonin. Thrombin is the strongest stimulant for the release of the contents of the dense granules, but other agonists for release have also been reported. The \(\alpha\)-granules are the largest and most prevalent storage granule, comprising the majority of the storage capacity of the platelet. They contain a number of proteins involved in platelet aggregation and cohesion, including fibrinogen, fibronectin, vWF, platelet-derived growth factor (PDGF), and platelet factor 4. Platelet lysosomes contain predominantly acid hydrolases, responsible for degradation of unwanted cellular debris after complete activation of fibrin formation.

Role of the Platelet in Hemostasis and Clot Formation

The platelet is the initial responder to vascular damage and subsequent endothelial exposure. Platelets rush to cover denuded endothelium, rapidly changing shape and providing an effective monolayer in what is known as the adhesion phase. This results in a primary platelet plug (primary hemostasis) that is responsible for preventing leakage of blood from the minute vessel defects that occur daily. If blood flow in this area remains nonturbulent, further platelet aggregation does not occur, and the monolayer generally suffices to plug the small defects or the area of vascular attenuation.\(^9\)

With large vessel disruption, blood flow becomes quite turbulent, resulting in large platelet aggregates coating the exposed endothelium. With the conversion of membrane-derived arachidonic acid to thromboxane \(A_2\), activated platelets release significant amounts of ADP.\(^10\) As an increasing number of platelets adhere and undergo conformational change, ADP levels in the local area increase (release reaction), strongly stimulating further platelet aggregation. Other agonists such as thrombin and epinephrine can also stimulate platelet aggregation. Prostacyclin, produced by neighboring healthy endothelial cells, prevents unwanted expansion of platelet aggregates by decreasing further ADP release. Platelet aggregation results in exposure of platelet factor 3, a platelet phospholipid, which serves as a congregation site for the coagulation factors.

The end result of coagulation-factor binding is the production of fibrin, which ultimately stabilizes the platelet plug (secondary hemostasis). In addition to platelet factor 3, platelets express receptors for factors Xa and Va, and for calcium, which is responsible for the conversion of prothrombin to thrombin. Platelets also contain many membrane glycoproteins (GPs) including GP IIb-IIIa, which is a receptor for vWF, and \(\alpha\)IIb\(\beta\)\(_3\), a fibrinogen receptor important for proper platelet aggregation. Manipulation of the glycoprotein receptors has become a focus of much research in an attempt to control the contribution of the platelet in thrombogenic disease processes. Platelets also play a critical role in the activation of the intrinsic coagulation pathway by providing binding sites for factors XIIa and XIa.

Platelets have critical roles in both primary and secondary hemostasis through the processes of adhesion, release reaction, aggregation, and activation of coagulation. As mentioned before, platelets have the ability to rapidly change shape and produce metabolic bursts that are responsible for the modulation of coagulation. From preventing leakage from minute vessel defects to initiation of thrombus formation, an appropriate number of properly functioning platelets is essential to the regulation of hemostasis.

Coagulation Factors

Coagulation factors are predominantly serine proteases (except factor XIII) that circulate in an inactive form throughout blood plasma. All coagulation factors, except for factor VIII, are produced in the liver. Factor VIII is produced by megakaryocytes. Activation of each coagulation factor is achieved through cleavage of a portion of the serine protease to reveal an active serine site. This results in the formation of macromolecular aggregates, the net result of which is fibrin formation. In physiologic activation of coagulation, the fibrin is cross-linked by factor XIII, resulting in stable clot formation at the site of a wound or an area of vascular injury. Properly coordinated fibrinolysis is responsible for clot removal and restoration of nutrient blood flow. The following discussion focuses on the characteristics of specific coagulation factors and the traditionally proposed pathways of the coagulation cascade.

It is useful to consider the coagulation factors as members of groups of proteins that share common characteristics or play a role in specific portions of clot formation.\(^12\) Most veterinarians are familiar with the vitamin K–dependent serine proteases, factors II, VII, IX, and X.\(^12\) Proteins C and
S. two anticoagulants, are also vitamin K dependent. All of these factors together are referred to as the prothrombin complex. Vitamin K is necessary for the carboxylation of glutamic acid, present on the serine protease, to γ-carboxyglutamic acid. This results in a double negative charge on the surface of the serine protease. This double negative charge facilitates an electrostatic bond with calcium (Ca$^{2+}$), which is essential for the binding of these molecules to platelet phospholipids.

A second family of proteins characteristically act as substrates for thrombin, or are principally involved in the final phase of clot formation. These are factors I (fibrinogen), V, VIII, and XIII. Activated factors V and VIII serve as cofactors for factors X and IX, respectively, and are essential in the amplification and acceleration of the coagulation cascade. Factor XIII, known as the fibrin-stabilizing factor, is responsible for cross-linking fibrin monomer strands and facilitating clot contraction. It is important to note that factors V, VIII, and XIII are extremely labile and are therefore commonly not present (or are present at very low levels) in stored blood products.

The remaining group of coagulation factors are those traditionally involved in the contact pathway of coagulation activation. This group consists of high-molecular-weight kininogen (HMWK), prekallikrein, and kallikrein, as well as factors XII and XI. Factor XII is a circulating single-chain glycoprotein that becomes activated through contact with collagen or a negatively charged surface. The activation of factor XII initiates the intrinsic pathway of coagulation. Prekallikrein is activated to kallikrein by activated factor XII. Kallikrein can have a significant amplification effect, activating factor XII as well as cleaving HMWK. These proteins form a complex that activates factor XI in the presence of calcium, ensuring continuation of the propagation of the intrinsic pathway. The complex may also be responsible for cross-activation of factor VII in the extrinsic pathway.

**Intrinsic Pathway**

As mentioned earlier, the intrinsic pathway is initiated by the activation of factor XII and subsequently factor XI through the exposure of blood to a negatively charged surface. Contact proteins such as HMWK and prekallikrein may also be involved in the amplification of the intrinsic pathway through activation of factors XII and XI, by appropriately positioning HMWK, prekallikrein, and factor XI close to surface-bound factor XII. Factor Xla (activated factor XI) in turn activates factor IX in the presence of calcium, presumably in the presence of the activated platelet membrane. Factor VIII, produced by megakaryocytes, becomes bound to vWF, but it circulates in an inactive complex VIIIa:vWF. Cleavage of this complex by thrombin results in the procoagulant activity of factor VIIIa. Factor IXa then binds to procoagulant VIIIa, in the presence of calcium. It is this complex that activates the common coagulation pathway, marked by the activation of factor X (Fig. 4-1).

**Common Pathway**

The common pathway is initiated by the activation of factor X, which, in the presence of factor Va, calcium, and a platelet phospholipid, converts prothrombin (factor II) to thrombin (IIa). In the final step of clot formation, factor IIa converts fibrinogen to fibrin. As mentioned earlier, factor XIII stabilizes the fibrin clot by cross-linking strands of fibrin monomer in the presence of calcium. Thrombin is capable of greatly amplifying the coagulation cascade by activating factors V, VII, and XIII, as well as by stimulating platelet activation.

**Extrinsic Pathway**

The extrinsic pathway is initiated by the activation of factor VII by tissue factor (TF). TF is present in vascular endothelium and a number of tissues, and it was initially thought to be exposed only secondary to damage or trauma. This explains the early hypotheses that the extrinsic pathway was less significant in physiologic hemostasis, as well as in the development of many types of hemostatic dysfunction. The role of TF was redefined after it was discovered that it commonly activates factor VII in the presence of endotoxin, trauma, and inflammatory mediators. It has been shown that TF levels are increased in disease states such as sepsis, diabetes, and atherosclerosis. Studies have shown that inhibition of TF in models of sepsis may improve the outcome and attenuate coagulopathies. It was recently demonstrated that protease-activated receptors (PARs) are the mediator between TF, factor VIIa, factor Xa complex, and the proinflammatory, procoagulant effects observed in endotoxemia. The results of this research have placed what is now commonly termed the tissue factor pathway (TFP) into a very prominent position in the study of hemostatic dysfunction in a number of disease processes. In fact, this
pathway is now also considered most important as the primary cellular initiation of coagulation.22

**Fibrinolysis**

Simultaneous activation of the fibrinolytic system occurs with activation of coagulation. This is the primary mechanism of clot dissolution and is responsible for prevention of excessive fibrin deposition and restoration of nutrient blood flow to affected tissues. Fibrinolysis, in conjunction with prostacyclin released by surrounding healthy endothelial cells, inhibits unwanted expansion of the fibrin clot.

Plasminogen, an inactive zymogen produced primarily in the kidney and liver, is the principal component of the fibrinolytic system. Plasminogen activators such as tissue plasminogen activator (tPA) and urokinase plasminogen activator (uPA) convert plasminogen to plasmin. Plasmin degrades fibrinogen and fibrin into soluble fibrin(ogen) degradation products (FDPs).24 The activation of the intrinsic pathway also activates plasminogen conversion to plasmin, through the action of kallikrein. Plasmin also serves to inactivate other members of the coagulation cascade, such as factors V and VIII, and actively degrades prekallikrein and HMWK. Through these mechanisms, plasmin serves not only to degrade fibrin(ogen) but also to downregulate the intrinsic pathway.

The products of fibrinogen or fibrin degradation are the FDPs designated fragment X, fragment Y, and fragments D and E.11 Fragments D and E have the ability to inhibit platelet aggregation and fibrin formation. Accumulation of these fragments in the blood represents an overwhelming of the mononuclear phagocytic system of the liver, the usual route by which these fragments are removed, either through increased fibrin production (and degradation) or liver dysfunction. Plasmin degradation of fibrin results in the formation of a neoantigen on the D fragment, which subsequently cross-links and is present in the circulation as a dimer (D-dimer). During the maintenance of physiologic hemostasis, a critical balance between fibrin formation and degradation exists. Proper functioning of the fibrinolytic system controls unwanted clot expansion, prevents premature fibrin lysis, and provides appropriately timed restoration of nutrient blood flow to tissues. Increased levels of FDPs, D-dimers, or soluble fibrin monomer in the circulation lead to increased fibrinolysis. This can be interpreted either as being the result of a thrombogenic disease process, or as the patient being in a hypercoagulable state.

**Inhibitors of Coagulation and Fibrinolysis**

**Inhibitors of Coagulation**

Inhibitors of coagulation are composed of a family of proteins that enzymatically bind with coagulation factors to form inactive complexes. In some instances, coagulation cofactors or surface receptors are destroyed to downregulate clot formation. The principal inhibitors of coagulation are antithrombin, heparin, protein C, protein S, and tissue factor pathway inhibitor (TFPI).

Antithrombin (AT) is responsible for 70% to 80% of thrombin inhibition in the coagulation system.10,24 It is the key player in a family of serine protease inhibitors responsible for modulation of clot formation. Antithrombin is a glycoprotein produced in the liver and in endothelial cells that binds aggressively to thrombin through an arginine-serine interaction.25 A stable thrombin–antithrombin (TAT) complex is the result of this reaction. The cofactor heparin alters the arginine site of AT and dramatically increases its ability to interact with thrombin. AT is also capable of neutralizing other serine proteases, such as factors Xla, Xla, Xa, and IXa. The AT–heparin complex also slowly inactivates factor VII.24 The horse appears to have higher concentrations of AT than some other species, such as dogs and humans.26 Currently, AT is commonly measured in horses suspected of having hemostatic dysfunction. AT loss may occur through consumption via increased thrombin formation, through protein loss, such as nephropathies or enteropathies, or via failure of adequate production.

Heparin is a highly sulfated glycosaminoglycan, ranging in molecular weight from 3 to 30 kDa.27 It is produced primarily in mast cells located in the lung, liver, kidney, heart, and gastrointestinal tract.26 In terms of physiologic anticoagulation, heparin’s most significant role is its ability to convert the interaction between antithrombin and thrombin from a slow reaction to a very rapid one. Its presence in an area of coagulation activation decreases thrombin-generated fibrin formation significantly. Heparin also releases TFPI from endothelial cells, thereby liberating one of the most effective inhibitors of the factor VIIa-TF complex.26,27 An additional proposed mechanism of heparin’s action may be the synergistic action of protein C, resulting in decreased production of thrombin through inhibition of thrombinase. The hemostatic relationship between vWF and the platelet is also affected by the presence of heparin, resulting in an additional antithrombogenic property. As a result of its many potential effects on coagulation, exogenous heparin administration has been a highly debated topic in the treatment of human and animal coagulopathies. Alterations of its chemical composition to enhance specific anticoagulant properties have been explored, resulting in the marketing of high- and low-molecular-weight heparins.27

The thrombomodulin–protein C–protein S pathway has received a lot of attention in recent years. Protein C is a vitamin K–dependent zymogen with primary inhibitory action on factors Va and VIIIa.30,26 For inhibition to occur, the reaction must take place in the presence of calcium, protein S, and phospholipid. Because these tend to be rate-limiting steps in clot formation, the end result of protein C is to limit thrombus size. In yet another negative-feedback mechanism, thrombin, in the presence of the endothelial cell cofactor thrombomodulin, is responsible for protein C activation.25 Deficits in this system may lead to hypercoagulability; for example, downregulation of the protein C pathway has been demonstrated in sepsis and the systemic inflammatory response syndrome (SIRS: see later and Chapter 2).

Tissue factor pathway inhibitor is a group of lipoprotein-bound proteins present in platelets and endothelial cells. As mentioned earlier, heparin enhances the release of TFPI into the circulation. In the presence of calcium, TFPI inhibits the factor VIIa-TF activation of factor X, thereby dramatically decreasing the primary cellular initiator of coagulation. Further exploration of TFPI and its activity in veterinary critical care patients is warranted.
**Inhibitors of Fibrinolysis**  
Plasminogen activator inhibitor (PAI) is the principal regulator of plasminogen, through inhibitory effects on tPA.\(^{28}\) PAI is present in endothelial cells and is stored in α-granules of platelets.\(^{29}\) The main physiologic inhibitor of plasmin is α-2-antiplasmin, through an almost instantaneous interaction.\(^{30}\) An alternative inhibitor of plasmin, α-2-macroglubulin, may inhibit plasmin in a limited fashion, particularly if α-2-antiplasmin is overwhelmed. Prevention of premature fibrinolysis and clot dissolution is mediated principally through these inhibitors of plasminogen and plasmin.

**HEMOSTATIC DYSFUNCTION**  
Hemostatic dysfunction is a clinicopathologic syndrome resulting from a multitude of underlying causes that clinically manifests as hypercoagulability, subclinical disseminated intravascular coagulopathy (DIC), or clinical DIC. There has always been a struggle to define the various stages of hemostatic dysfunction; specific definitions of DIC vary from report to report. Scoring systems for DIC have been proposed\(^{30,31}\) but have not gained widespread use, and they would have to be modified for use in veterinary medicine.

It is perhaps best to consider hemostatic dysfunction as a progressive failure of various arms of the hemostatic system. Clinical (or overt, noncompensated or fulminant) DIC may start as multiple microvascular or large- vessel thromboses, possibly a result of hypercoagulability and decreased fibrinolytic activity, which progress to body cavity hemorrhage and complete failure of primary and/or secondary hemostasis. To help distinguish these phases of dysfunction, hypercoagulability is now commonly described as a specific clinical entity, and a distinction exists between subclinical DIC (compensated, non-overt) and clinical DIC (overt, noncompensated).\(^{32}\) (On the other hand, hypercoagulability is often not described as a specific clinical entity but is instead a feature of progression into stages of pathologic coagulopathy.)

Clearer definitions of the phases of hemostatic dysfunction have led to attempts to identify DIC in its earlier stages in hopes that prompt intervention will improve the outcome.\(^{33}\) That hemostatic dysfunction increases morbidity and mortality in critically ill human and animal patients is well established, but the exact mechanism of what specifically occurs on a microvascular level is still debated. Most investigators now agree that hemostatic dysfunction and its subsequent clinical syndromes are a component of SIRS, and that ensuing organ failure is the most common cause of death in affected patients.\(^{34}\) For equine veterinarians struggling with patients that are extremely endotoxin sensitive, the challenges continue to be early detection of patients at risk and the search for effective anticoagulant or component therapy to restore physiologic anticoagulant pathways.

**Hypercoagulability**  
Hypercoagulability, commonly defined as thrombosis formation in inappropriate locations, can be primary or secondary.\(^{35}\) In humans, the primary causes of hypercoagulability often include specific deficits in anticoagulants, such as antithrombin, protein C, and protein S, or dysfunction of the fibrinolytic system.\(^{36,37}\) Primary causes of hypercoagulability in veterinary patients are certainly not prevalent in the literature. Secondary causes of hypercoagulability in human patients include diseases or conditions such as malignancy, pregnancy, nephrotic syndrome, platelet abnormalities, or abnormalities of blood vessels and rheology.\(^{38}\) Again, these secondary causes of hypercoagulability are not commonly reported in veterinary patients. Typically, hypercoagulability observed by veterinarians relates to an early procoagulant phase of hemostatic dysfunction, which may or may not progress to DIC. In this sense, the recognition of hypercoagulability is critical in the prevention of significant thrombotic disease, or in the development of organ dysfunction.

Hypercoagulability is a response to inflammation initiated by a primary disease process (Fig. 4-2). An endotoxin challenge increases cytokines such as interleukin-6 and interleukin-8, which may be responsible for the initiation of a procoagulant state through the activation of the tissue factor pathway.\(^{39}\) The activation of the hypercoagulable state can be triggered by endothelial damage or TF activation, and, depending on the cross-reactivity of activated serine proteases, inhibition of the fibrinolytic system may occur simultaneously. Although there is not a readily agreed-on set of tests for the diagnosis of hypercoagulability, alterations in certain parameters may identify hypercoagulation as a component of early DIC. In a study evaluating hemostatic markers prior to the onset of DIC, increases in soluble fibrin monomer, D-dimer, and thrombin–antithrombin (TAT) were useful indicators of the onset of coagulopathy,\(^{40}\) and their presence seemed to indicate an ongoing increase in clot formation. Viscoelastic measures of clot formation, such as thromboelastography (TEG) or the Sonoclot Platelet Function Analyzer (Sonoclot Coagulation and Platelet Function Analyzer, Sienco, Wheat Ridge, Colo.) could be used clinically for early identification of a hypercoagulable state. Otto and colleagues successfully used TEG to demonstrate hypercoagulability in dogs with parvoviral enteritis.\(^{41}\) Trials using viscoelastic techniques are ongoing in both small- and large-animal applications for identification of hypercoagulability and earlier recognition of hemostatic dysfunction.

**Disseminated Intravascular Coagulation: Identification of Patients at Risk**

Hemostatic dysfunction may progress to DIC in the equine patient as a result of severe endotoxemia, neoplasia, sepsis, acute trauma or hemorrhage, or possibly the syndrome of hypoxia-ischemia encephalopathy observed in neonates. Reports of DIC in the equine veterinary literature most commonly describe the process as occurring secondary to a primary gastrointestinal disorder.\(^{42}\) As mentioned earlier, the definition of DIC varies significantly in the human critical care literature. Most reports in the veterinary literature describe clinical DIC, in which the horse had overt clinical signs, or subclinical DIC, in conjunction with an abnormal coagulation profile but lacking signs of a thrombohemorrhagic crisis.

Reports of horses with clinically overt DIC describe the process as occurring secondary to neoplasia, sepsis, or severe

gastrointestinal disease. Clinical signs in these patients included excessive hemorrhage during surgery, bleeding from venipuncture sites, venous thrombosis, and petechiae. Survival rates for horses with clinical DIC secondary to gastrointestinal disorders range from 34% to 67%, with outcomes worse for horses with severe ischemic bowel disease. There appears to be an association between the development of a coagulopathy and a devitalized small intestine in the horse. Large-colon torsion has also been associated with hemostatic dysfunction and poor outcome.

A larger prospective study (N = 233) evaluated eight parameters of hemostasis. Parameters associated with increased coagulation and fibrinolysis were observed (decreased AT, protein C, and plasminogen; increased prothrombin time (PT), activated partial thromboplastin time (APTT), and fibrin degradation products). Because this study was designed prospectively, all initial hemostatic parameters were observed to be abnormal in patients that had not received a clinical diagnosis of DIC. Failure of parameters to return to normal was associated with the development of overt DIC. This study demonstrated early evidence of subclinical DIC in horses with gastrointestinal disease, suggesting coagulation testing should be performed in these at-risk patients.

Documentation of subclinical DIC in horses with colitis has been reported. Approximately one third of horses with colitis presenting to a veterinary teaching hospital were diagnosed with subclinical DIC. Horses were eight times
more likely to die if identified as having subclinical DIC. In one study, 70% of horses with surgical treatment of large-colon volvulus had subclinical DIC.\textsuperscript{55,49} None of the horses had a coagulation profile ordered as part of perioperative management. Horses were more likely (odds ratio, 47:1) to be euthanized if four to six hemostatic parameters were abnormal in the postoperative period.

Young foals (less than 1 week of age) have also been reported to have alterations in hemostatic indices.\textsuperscript{50} Foals with presumed septicemia are even more likely to develop a coagulopathy.\textsuperscript{51} In our hospital, foals with severe hypoxic-ischemic encephalopathy undergoing a systemic inflammatory response have had abnormal hemostatic parameters.

The surgeon needs to be aware that very young or sick neonates, and horses with neoplasia, sepsis, or severe gastrointestinal disease, are at risk for development of DIC. Perhaps more critically, many at-risk patients develop subclinical DIC, the presence of which may not be obvious but could definitely affect surgical outcome. Identification of subclinical DIC through perioperative coagulation testing in patients at risk could allow appropriate surgical planning and postoperative management.

Coagulation Testing
A standard coagulation profile in our hospital consists of platelet count, PT, PTT, AT, FDPs, and fibrinogen. However, coagulation profiles vary from hospital to hospital, as do normal values established by each laboratory.

Platelet Count
Horses tend to have lower platelet counts than other species, typically in the 150,000 to 250,000/µL range. A platelet count of less than 100,000/µL is considered abnormal. In the literature on humans, thrombocytopenia is a consistent feature of acute coagulopathy, but it may not be present in chronic or compensated DIC. Thrombocytopenia was reported in ponies in a model of severe intestinal strangulation,\textsuperscript{43} and it was also a feature of almost half of horses with colitis that developed subclinical DIC.\textsuperscript{47} In horses surgically treated for large-colon volvulus, development of thrombocytopenia was significantly associated with poor outcome.\textsuperscript{55}

Given the integral role of the platelet in hemostasis, it is understandable that severe thrombocytopenia has an effect on a number of different portions of the coagulation cascade. Not only should a patient have adequate platelet numbers but proper function of the platelets is also critical. Viscoelastic analyzers of clot formation may provide more sensitive information about platelet function, although studies are needed to further evaluate these methods in the equine patient. Petechiae or hemorrhagic oozing of mucosal surfaces are clinical signs of thrombocytopenia.

Prothrombin Time
Prothrombin time is used to evaluate the extrinsic and common pathways of the coagulation cascade. Typically, an increase in time by 20% indicates an abnormal test result. In DIC in humans, PT may not be a particularly useful indicator,\textsuperscript{52} perhaps because of a lack of sensitivity when there is significant clinical decline, or perhaps because more sophisticated molecular markers, not commonly available in the veterinary clinical setting, are relied on. In human patients, PT becomes prolonged when fibrinogen is less than 100 mg/dL, prothrombin is less than 30% of its normal plasma concentration, or factors VII, V, and X are decreased to 50% of their normal concentrations.\textsuperscript{53}

Prolonged PT was observed only in a portion of horses presenting for colic, but it appeared to be a good predictor of outcome.\textsuperscript{42,43} Prolongation of PT was associated with horses that had strangulating gastrointestinal lesions in another study.\textsuperscript{46} In horses with surgical treatment of large-colon volvulus, prolonged PT was associated with poor outcome.\textsuperscript{45}

Activated Partial Prothrombin Time
A prolonged PTT indicates dysfunction of the intrinsic coagulation pathway. An increase in time by 20% is usually considered abnormal, as seen with PT. PTT is not a particularly useful indicator of DIC in human patients, and it often becomes abnormal when factor VIII or IX is decreased by at least 20%. PT and PTT are also prolonged in people with a fibrinogen level of less than 100 mg/dL,\textsuperscript{52} but this would be an uncommon cause of prolongation in the equine patient.

In reports of hemostatic analysis of horses with colic, PTT prolongation was one of the most common findings,\textsuperscript{42,44,46} but it was not predictive of patient outcome. Similarly, horses with colitis that developed subclinical DIC often had prolonged PTT, but there was no association with patient outcome.\textsuperscript{57}

Both PT and PTT serve as parameters to evaluate the coagulation cascade portion of the hemostatic system. Although PT and PTT are certainly useful indications of significant problems with the coagulation cascade, they may not be sensitive enough to adequately identify early stages of hypercoagulability or DIC. Prolonged PT or PTT may be associated with body cavity bleeding, significant hematuria, or hematochezia. Perhaps wider availability of more specific molecular markers of coagulation will provide the veterinary clinician with earlier clinical data for the diagnosis of hemostatic dysfunction.

Antithrombin
As discussed earlier, AT is one of the most significant and effective serine protease inhibitors in the anticoagulative armamentarium. Much attention has been given to measuring levels (reported as percentage activity) of AT in the human critical care literature, and a poor outcome is expected when AT drops to 60% to 70%. In human cases of DIC or sepsis, AT drops as a result of consumption, or because of destruction by elastase produced by activated neutrophils.\textsuperscript{54} Other possible causes for decreased AT activity are protein loss (enteropathy or nephrotic syndrome) and failure of production. AT activity appears to be a more sensitive indicator of an ongoing coagulopathic problem, and many animal studies have reported improvement with the administration of AT concentrate in models of endotoxemia and sepsis.

In the equine patient with acute gastrointestinal disease, AT has been shown to be a useful predictor of outcome.\textsuperscript{49,46}
In one study of horses with large-colon torsion, the patients had a significant decrease in AT, and failure for AT to return to normal activity was associated with nonsurvival.\(^{55}\) AT was significantly greater in the peritoneal fluid of nonsurvivors presenting with acute gastrointestinal disease,\(^{49}\) indicating a dramatic AT response to intraperitoneal inflammation and a possible decrease in systemic AT circulation. Horses with colitis developed AT deficiency approximately 48 hours after admission, in association with hypoproteinemia.\(^{57}\) AT levels in the horse are normally greater than in some other species, and it appears that a significant decrease in AT can reliably predict hemostatic dysfunction.

**Fibrin(ogen) Degradation Products**

FDPs are produced by the proteolytic degradation of fibrin(ogen) by plasmin. They are routinely cleared by the mononuclear phagocytic system (MPS), and an accumulation of FDPs indicates a failure of the MPS to adequately remove them from the circulation. This can be the result of local or systemic hyperfibrinolysis, and it may be indicative of a dramatic increase in clot formation. FDP evaluation is usually performed as a semiquantitative test, resulting in the following possible ranges for FDPs: 0 to 10 \(\mu\)g/mL, 10 to 20 \(\mu\)g/mL, 20 to 40 \(\mu\)g/mL, or greater than 40 \(\mu\)g/mL. In our clinical laboratory, FDPs greater than 10 \(\mu\)g/mL are considered abnormal.

In reports evaluating the predictive value of hemostatic parameters in the equine patient, FDPs were often increased but poorly predictive of development of DIC or patient outcome.\(^{42-47}\) It is possible that in an animal that produces rather large amounts of fibrinogen in response to inflammation, FDPs are not particularly useful indicators of development of a coagulopathy or of poor outcome.

**Fibrinogen**

The measurement of fibrinogen as part of a standard coagulation profile is an attempt to document hypofibrinogenemia, which is a somewhat consistent feature of overt DIC in humans. It is not unusual for human patients with significant hemostatic dysfunction to develop a fibrinogen level of less than 100 mg/dL. This does not seem to be a consistent finding; however, there was a difference in the fibrinogen levels between the DIC and non-DIC groups.\(^{47}\) Similarly, horses surgically treated for large-colon volvulus and horses suffering from DIC associated with a poor outcome demonstrated lower fibrinogen levels than their surviving counterparts with better hemostatic function. In the horse, perhaps it is the failure of expected fibrinogen increase, rather than the development of hypofibrinogenemia, that could be significant. Further studies are needed to validate this hypothesis.

For both human and veterinary patients, the problem continues to be achieving prompt and accurate identification of hemostatic dysfunction early enough to intervene successfully. By the time many of the standard coagulation tests, such those discussed earlier, are significantly abnormal, the therapeutic window of opportunity has often narrowed. It is possible that additional tests of hemostatic dysfunction could provide earlier detection and subsequent intervention.

There is no one specific test that best identifies DIC in the horse. In patients at risk for development of a coagulopathy, a standard coagulation profile should be performed. The parameters that are abnormal relate to both the primary disease and the specific host response to the insult. Although variations in the coagulation profile abnormalities may exist, the profile may point to the component of hemostasis that is most affected, and this could be used to guide therapy. Increased FDPs, decreased fibrinogen, and decreased AT may indicate hypercoagulability. These three abnormal hemostatic parameters indicate subclinical DIC, and they should direct the clinician to take action. Earlier intervention, prior to the onset of clinical DIC, may improve outcome.\(^{51}\)

Currently, no prospective study is available that compares treatment options for DIC and outcome. Therapy should be aimed at restoration of physiologic hemostasis. Administration of fresh frozen plasma, with or without the addition of heparin, can replace depleted coagulation factors and potentiate the action of AT. Heparin therapy alone may decrease hypercoagulability, although side effects such as thrombocytopenia and anemia are common in the horse treated with repeated doses of unfractionated heparin. Platelet-rich plasma could be used in patients with thrombocytopenia caused by consumption. Hemostatic tests available for veterinarians in a clinical setting are somewhat limited, and debates over proper therapy are common. Performing a standard coagulation profile provides the clinician with the opportunity to attempt to restore physiologic hemostasis, prepare for possible overt DIC and organ dysfunction, and inform the client about a possible poor outcome.

**Additional Tests of Hemostatic Dysfunction**

Measuring D-dimer is not a particularly new hemostatic test, but it is often not included in coagulation profiles performed in the equine surgical setting. D-dimer is an epitope resulting from the plasmin degradation of fibrin. It is a cross-linked dimer of the two smallest fibrin degradation products, fragment D-D. D-dimer can be measured semiquantitatively by latex agglutination, or by using a latex-enhanced turbidimetric immunoassay performed on a standard coagulation analyzer. Increased D-dimer levels indicate increased fibrinolysis or inability to clear the products from the circulation. In critically ill patients, D-dimer has been used to better characterize acute pulmonary thromboembolism, and to diagnose deep vein thrombosis.

D-dimer concentrations were evaluated in healthy dogs and dogs with DIC.\(^{50}\) D-dimer was found to be a sensitive and specific test for the identification of dogs with DIC. In this study, DIC was defined as thrombocytopenia in combination with two additional abnormal hemostatic parameters and bleeding from at least two unrelated sites. D-dimer has also been reported to improve the prognostic value of...
clinical and laboratory data in horses with acute colic. It is possible that the predictive value may be linked to the prognosis of specific types of gastrointestinal lesions. In a study evaluating D-dimer in horses surgically treated for large-colon volvulus, D-dimer was significantly increased in all patients. D-dimer could not be used to distinguish survivors from nonsurvivors, nor was it useful in predicting which horses had abnormal coagulation profiles. It can be stated that D-dimer must be evaluated while considering the primary cause of the inflammatory process. If the primary lesion involves ischemic or strangulating circumstances, D-dimer may be reflective of the inciting event rather than predictive of the development of DIC or mortality.

Thrombin-antithrombin is an irreversible inactive complex between thrombin and antithrombin. TATs are rapidly taken up by a serpin-1 receptor and quickly degraded by the liver, resulting in a short half-life of 5 minutes. TAT levels can be measured using a sandwich enzyme-linked immunosorbent assay (Enzygnost, Dade-Behring, Inc., Wilmington, Del.), which has been evaluated and validated for use in the horse.

TAT complexes have been measured in horses with colic and reveal a significant increase in TAT in nonsurvivors. The most significant increase in TAT level between nonsurvivors and survivors was observed on the admission sample. Horses with strangulating obstructions had significantly higher TATs than horses with nonstrangulating lesions over time. In a study evaluating TAT complexes in horses with surgical treatment of large-colon volvulus, increased TATs were associated with the development of DIC and poor outcome. A statistically significant difference was observed at all three time points between survivors and nonsurvivors. Although measuring TAT complexes seems quite promising for predicting both the development of DIC and poor outcome, the TAT complex remains difficult to use in a clinical setting. Hopefully, a SNAP ELISA TAT kit will be developed in the near future, increasing the applicability in the clinical situation.

Viscoelastic analyzers may hold some promise for evaluation of coagulation in the veterinary surgical patient in the future. Thromboelastography and the Sonoclot analyzer are two currently available analyzers that use viscosity and/or elasticity to evaluate clot formation in whole or citrated blood samples. Both analyzers evaluate all phases of clot formation and retraction from a single, small-volume (i.e., 300 µL) sample of blood. A tracing or signature is provided from which values can be derived to assess platelet or coagulation function. Software is provided with each analyzer, resulting in a user-friendly interface and easy storage of data.

In human surgical patients, viscoelastic analyzers are most commonly used to monitor coagulation inhibition during cardiopulmonary bypass procedures and liver transplantsations, and to evaluate perioperative hemorrhage. TEG has been used to identify a hypercoagulability state in dogs with parvoviral enteritis. In our clinic, we are using the Sonoclot analyzer for hemostatic evaluation of septic foals, and we are initiating a study to use the analyzer to assess coagulopathy in horses with surgical treatment of acute colic.

SURGICAL BLEEDING

An increased risk for surgical bleeding may be related to an inherited condition in the patient or to an acquired coagulopathy or thrombocytopathy, or it may be a consequence of the procedure being performed. In equine surgery, it is probably most commonly related to an acquired hemostatic dysfunction or the nature of the surgical procedure.

Predisposing Factors

Inherited conditions that result in coagulopathy or thrombocytopathy are relatively uncommon in the horse and much more common in the dog, cat, and human. These conditions include von Willebrand disease, thrombasthenia, hemophilias, and specific coagulation factor deficits. In horses, deficits of prekallikrein and of factors VIII, IX, and XI have been reported. These may be difficult to detect preoperatively; a thorough history obtained from the client or observation of clinical signs may indicate a need for specific coagulation testing. If a specific deficit is identified, adequate preparation for surgery is critical, possibly consisting of pretreatment with component therapy or anticoagulants.

Acquired conditions resulting in hemostatic dysfunction may present clinically as DIC, or perhaps as a specific coagulopathy or thrombocytopathy. Primary diseases that could result in DIC (see earlier) and that may be encountered by a surgeon include neoplasia, sepsis, trauma, severe acute hemorrhage, clostridial myositis, and severe endotoxemia associated with acute gastrointestinal disease. Hemostatic dysfunction could also be the result of inappropriate use of heparin (particularly unfractionated), aspirin, or other anticoagulants. The administration of certain drugs such as sulfonamides, penicillin, phenylbutazone, ibuprofen, estrogens, antihistamines, and cardiovascular drugs has been associated with thrombocytopenia in humans and animals. Other diseases associated with hemostatic dysfunction in the horse are severe liver disease, equine infectious anemia, Anaplasma phagocytophilum, and equine viral arteritis. In general, if any acquired condition that could result in a coagulopathy is noted in the history or detected in the clinical progression of a surgical candidate, appropriate and complete evaluation of the hemostatic system must be performed. If the surgeon is presented with an emergent situation, arrangements should be made for the availability of a blood donor or possible component therapy to attenuate the situation.

Certain surgical procedures, particularly in large-animal surgery, are associated with a significant risk for intraoperative and postoperative hemorrhage. Surgery involving the sinuses or ethmoid area, the cranial reproductive tract, the spleen, or certain neoplasias may result in significant intraoperative hemorrhagic challenges. Because many of these surgeries can be performed electively, careful preoperative planning may alleviate many of the complications of perioperative hemorrhage. Options could include planned autologous transfusion and normovolemic or isovolemic hemodilution, preoperative crossmatch and subsequent whole blood transfusion (see later), or availability of stored blood products and components. Autologous transfusion and normovolemic hemodilution involve collection of the
patient’s blood in the weeks before surgery (banking) or in the immediate preoperative period, followed by administration of crystalloids prior to induction. Recombinant human factor VII has been used in human surgeries both in trauma situations to decrease life-threatening hemorrhage and as a preoperative procoagulant treatment. Throughout any surgical procedure, it is critical to employ proper hemostatic techniques.

**BLOOD TRANSFUSION**

The need for blood transfusion in the horse is usually a result of acute blood loss, secondary to either trauma or surgical intervention, or of severe hemolytic anemia, possibly caused by neonatal isoerythrolysis, red maple leaf toxi-cosis, or immune-mediated thrombocytopenia. Acute blood loss is the situation the surgeon most commonly faces.

Deciding when to transfuse is not easy, and the issue has been debated in both human and veterinary medicine. Transfusions are not without risk, and their pros and cons must be carefully considered. Guidelines regarding this decision fall roughly into three categories: physiologic indicators, indices of red cell mass, and clinical observations. Ultimately, the attending clinician decides when a transfusion is best for the patient, and the clinical situation often plays a large role in the decision. The veterinary surgeon may ask the following questions: Is the patient still bleeding? What is the duration of the blood loss? What are the wishes of the owner? What is the animal’s overall prognosis with regard to the primary lesion? Are there reasonable alternatives to transfusion in this patient? Good clinical judgment is just as critical as any single measure to determine the need for perioperative transfusion.

Acute blood loss in the horse can be the result of splenic trauma, uterine artery bleeding, guttural pouch mycosis, or a surgical procedure associated with high risk for hemorrhage. In the event of acute blood loss, the goal is to maintain appropriate oxygen delivery (DO₂) to the tissues. Tissue oxygen delivery is controlled by cardiac output, which affects the volume of blood reaching the tissue, and the oxygen content of the blood reaching that tissue (CaO₂). The first challenge of acute blood loss is the decline in intravascular blood volume, which results in decreased stroke volume and subsequent decrease in cardiac output. As the body loses red cell mass, the oxygen-carrying capacity of the intravascular blood volume decreases. This means tissue oxygen delivery takes a second hit, decreased CaO₂ combined with poor perfusion. The results of inappropriate tissue oxygenation are anaerobic cellular metabolism, increased lactate production, subsequent cellular dysfunction, and probable organ dysfunction and death.

The physiologic response to acute blood loss is immediate redirection of blood flow to essential organs, such as brain, heart, kidneys, and lung (see Chapter 1). The initial drop in intravascular blood volume triggers arterial baroreceptors to increase heart rate and respiratory rate, and vasoconstriction of peripheral vessels. Vasoconstriction is rather profound in splanchnic beds, which results in a significant recruitment of blood volume. In the horse, the spleen may contain up to 30% of the circulating red cell mass, and splenic contraction is triggered within minutes of an acute hemorrhagic episode. Other compensatory mechanisms include fluid shift from interstitial to intravascular spaces, a shift of the oxyhemoglobin curve to the right, increased levels of 2,3-diphosphoglycerate, antidiuretic hormone increase, and activation of the renin-angiotensin-aldosterone system.

**Indications**

Determining when to transfuse is difficult because tissue oxygenation cannot be easily monitored in veterinary patients. Clinicians would welcome a specific guideline that tells when to give a transfusion. However, the degree of acute anemia cannot be appropriately assessed by the PCV, hematocrit, or hemoglobin concentrations and will be normal until fluid shifts occur. These hematologic values reflect only a relative concentration of the entire intravascular volume. A number of circumstances, such as crystalloid fluid volume resuscitation or rate of hemorrhage, could make these values difficult to interpret.

Physiologic monitoring of the human patient with acute hemorrhage often involves pulmonary artery catheter placement and measurements of systemic oxygenation saturations and oxygen extraction ratios. The oxygen extraction ratio (O₂ ER) is the ratio of oxygen uptake to oxygen delivery, and it represents the utilization of oxygen by the tissues. Normal O₂ ER is approximately 0.2 to 0.3, or 20% to 30%. As the value for O₂ ER increases, tissues extract a larger portion of the oxygen supplied by the afferent vasculature. Because mixed venous oxygen saturation returning to the pulmonary artery contributes to the systemic arterial concentration, a high O₂ ER represents a continual decline in tissue oxygenation. The O₂ ER may adjust to physiologic circumstances. In trained athletes, it may be up to four times the normal value as the metabolic demands for oxygen dramatically increase. Generally, once the O₂ ER reaches 0.5 in a patient with hemorrhage, tissue oxygenation is impaired, and transfusion is indicated.

In most veterinary clinics, a pulmonary artery catheter is not an option, but O₂ ER can be estimated using pulse oximetry to determine arterial oxygen saturation (SaO₂), and a central venous pressure catheter to estimate mixed venous oxygen saturation (SvO₂), and by calculating as follows:

\[
O₂ \text{ ER} = \sim \frac{SaO₂}{SvO₂}
\]

Using O₂ ER as an assessment of tissue oxygenation is a more accurate method than relying solely on a specific red cell index such as PCV or hemoglobin. Currently, there are no guidelines for use in the horse; but pulse oximetry and a central venous pressure catheter can be used to estimate O₂ ER. The red cell index that indicates transfusion in humans is hemoglobin below 6 or 7 g/dL, which corresponds to a hematocrit of less than 18% to 21%. A number of additional patient considerations are recommended for use with that numerical cutoff, such as rate of hemorrhage, illness of patient, clinical signs, increased lactate, additional evidence of organ dysfunction, and the O₂ ER.

Recommendations for transfusion in the equine patient are a PCV of less than 20% in an acute bleeding episode, or less than 12% to 14% in a situation of chronic blood loss.
However, during acute bleeding, the PCV will be normal. Therefore, clinical signs associated with acute hemorrhage that may indicate evidence of hypovolemic shock include tachycardia, tachypnea, poor pulse quality, poor perfusion to extremities, poor jugular fill, and pale mucous membranes (see Chapter 1). Indirect blood pressure measurements can be taken, but they have been inaccurate in human patients with hypovolemic shock. Direct blood pressure measurements through an arterial line may be useful in determining the need for transfusion and for measuring the response to fluid volume resuscitation, but blood pressure may remain normal as it is the last parameter to alter before death. Integrating all the available information (clinical signs, red cell indices, and physiologic parameters) is the best approach to determining the need for transfusion.

Donor Selection and Management

Unfortunately, a universal equine donor does not exist. Horses have seven blood categories: A, C, D, K, P, Q, and U, with alloantigen subdivisions. It is desirable for a blood donor to be Aa and Qa alloantigen negative, as these types are the most immunogenic of the identified red cell antigens. It is also helpful if a donor is negative for Aa alloantibodies, given the prevalence of the Aa type. If the blood type is unknown, and a crossmatch is unavailable, a Standardbred or Quarter Horse gelding may be the best option for a donor, as either is less likely to have Aa and Qa alloantigens. Donors should weigh at least 450 kg and be in good health. Mares that have foaled are a poor selection as donors, because they may have developed specific blood type alloantibodies during pregnancy. The donor should be negative for transmissible bloodborne diseases, such as equine infectious anemia, and should not have received any transfusions.

In a veterinary teaching hospital or a large practice setting, blood typing of a group of available donors can be very helpful. Where available, a crossmatch providing evaluation of agglutinins and hemolysins significantly minimizes the risk of transfusion reactions. Alloantibodies in the horses often act as hemolysins. This means lysis studies using rabbit complement are very helpful in determining the compatibility of a donor. The major portion of the agglutination phase of the crossmatch involves washing the donor’s red blood cells with the recipient’s serum. The minor portion consists of washing the recipient’s red cells with the donor’s serum. Optimal compatibility is determined by selecting the donor with the least reactivity in all three categories, with the minor being of the least significance.

The amount of blood being collected from the donor is determined by the needs at the time of donation and the physiologic limitations of the donor. Recommendations for volume collected from the donor vary from 16% to 30% of total blood volume, but recent studies favor 25%. In a typical-size donor, 25% of blood volume usually results in about 10 L, which can reasonably provide the recipient with improved tissue oxygenation in most situations. The long- and short-term effects of collecting 25% of a horse’s blood volume were recently evaluated, and it was found to be quite safe. Cardiovascular and physiologic parameters were rarely outside the normal range, and they returned to precollection values within 24 to 48 hours. This volume can be safely collected from a donor every 30 days.

To determine an approximate volume of blood needed for transfusion, the following formula is often used:

\[
\text{desired PCV} = \frac{\text{recipient PCV} \times (0.8 \times \text{body weight [kg]})}{\text{PCV of donor}}
\]

This formula assumes that the recipient has approximately 80 mL of blood volume per kilogram of body weight (thus the 0.8 value). A higher value may be used if a larger blood volume per kilogram is suspected—for example, in a neonatal patient requiring transfusion.

Blood Collection and Administration

Blood is most effectively collected in 3-L plastic bags using an intravenous transfer set. Glass bottles are easily broken, and they may stimulate contact coagulation or platelet dysfunction during collection. The vacuum on many glass collection sets may also damage the red cells. The most commonly available anticoagulants are acid-citrate-dextrose (ACD) and citrate-phosphate-dextrose (CPD). The anticoagulant-to-blood ratio should be 1:9.

Blood is usually administered through an aseptically placed jugular catheter. A blood administration set with filter is recommended for transfusion. Whole-blood administration should be started at a slow drip, and temperature, heart rate, and respiratory rate should be monitored for 15 minutes. If no adverse reactions are observed, the transfusion can proceed at a target rate of 10 to 20 mL/kg.

Complications of Transfusion

Tachycardia, tachypnea, sweating, signs of distress or discomfort, urticaria, and sudden collapse are all signs of anaphylaxis. If any of these signs occur, transfusion should be stopped immediately and an anti-inflammatory dose of flunixin meglumine or steroids administered. If signs of anaphylaxis are evident, 0.01 to 0.02 mL/kg of a 1:1000 concentration of epinephrine should be administered.

Risks of transfusion include hemolytic reactions and hypersensitivities, acute lung injury, and immunosuppression. Recent reports indicate that transfusions may result in an immunomodulatory response that could affect the surgical outcome. An increase in nosocomial infections has been observed in critically ill patients that have received transfusions. In small-animal surgical patients, transfusion was identified as a risk factor in the development of aspiration pneumonia and acute respiratory distress. The immunomodulatory effects of transfusion are not completely understood, but evidence exists that an impaired immune system is a possible complication.

PLASMA TRANSFUSION

Plasma is administered in the horse in hyperimmunized forms for specific diseases or endotoxemia, or for replacement of clotting factors. It is also used in cases of hypalbuminemia, but this is not always a cost-efficient method of increasing colloid oncotic pressure in the horse. Plasma hyperimmunized against Rhodococcus equi and the Escherichia
coli mutant J5 portion of endotoxin is available commercially. For the equine surgeon, the most common uses of plasma transfusion are to treat acute endotoxemia and to replace clotting factors in cases of DIC or acute hemorrhage. The dose of plasma administration in these applications is 4 to 5 mL/kg, but if restoration of physiologic anticoagulants is a goal of such an administration, hemostatic monitoring should follow plasma therapy. Administration of plasma should be through a blood administration set, and horses should be monitored for any signs of reaction, although hypersensitivity reactions to plasma are uncommon. Fresh frozen plasma may be obtained via immediate plasmapheresis from individual units of whole blood, and it can be stored for approximately 1 year if frozen properly. Fresh frozen plasma contains the most viable clotting factors, and it is the plasma product of choice when there is any coagulopathy or specific factor deficit.

Platelet-rich plasma (PRP) can be produced by centrifugation of whole blood at a rate of 250 x g or by more sophisticated methods of thrombocytepheresis available at human hospitals or blood banking facilities. PRP administration may be quite useful in cases of immune-mediated thrombocytopenia or thrombocytopenia, or in cases of dilutional coagulopathy secondary to acute hemorrhage.

CHAPTER 5

Wound Repair
Christine L. Theoret

A critical trait of living organisms continually subjected to insults from the environment is their capacity for self-repair. Whether the injury is a deliberate act of surgery or accidental, it generates an attempt by the host to restore tissue continuity. Two processes are involved in healing: repair and regeneration. Repair entails the replacement of damaged tissue with normal cells of the type lost, and this is possible only in tissues with a sustained population of cells capable of mitosis, such as epithelium, bone, and liver. Repair is a stopgap reaction designed to reestablish the continuity of interrupted tissues. Tissue forms between the severed parts, without differentiating totally new elements, and ultimately results in scar tissue. Repair is therefore the second-best method of healing, producing a result that is usually less biologically useful than the tissue it replaced and that may adversely affect adjacent normal tissues.

Traumatic wounds occur commonly in horses and often demand labor-intensive and costly treatments. The objective of repair is reestablishment of an epithelial cover and recovery of tissue integrity, strength, and function. Partial-thickness wounds (e.g., abrasions and erosions) heal primarily by migration and proliferation of epidermal cells...

Wound Repair
Christine L. Theoret

A critical trait of living organisms continually subjected to insults from the environment is their capacity for self-repair. Whether the injury is a deliberate act of surgery or accidental, it generates an attempt by the host to restore tissue continuity. Two processes are involved in healing: repair and regeneration. Repair entails the replacement of damaged tissue with normal cells of the type lost, and this is possible only in tissues with a sustained population of cells capable of mitosis, such as epithelium, bone, and liver. Repair is a stopgap reaction designed to reestablish the continuity of interrupted tissues. Tissue formation between the severed parts, without differentiating totally new elements, and ultimately results in scar tissue. Repair is therefore the second-best method of healing, producing a result that is usually less biologically useful than the tissue it replaced and that may adversely affect adjacent normal tissues.

Traumatic wounds occur commonly in horses and often demand labor-intensive and costly treatments. The objective of repair is reestablishment of an epithelial cover and that may adversely affect adjacent normal tissues.

from the remaining underlying epithelium as well as the adnexal structures (hair follicles, sweat and sebaceous glands), with little participation of inflammatory or mesenchymal cells. In contrast, repair of full-thickness wounds relies principally on three coordinated phases: acute inflammation, cellular proliferation, and, finally, matrix synthesis and remodeling with scar formation (Fig. 5-1). Many traumatic wounds in horses, whether partial- or full-thickness, cannot be sutured because of massive tissue loss, extreme contamination, continuous movement, and skin tension, as well as a long interval since the time of injury. A further number dehisced after attempted primary closure, for similar reasons. A large retrospective study revealed that primary closure was successful in only 24% of horse wounds and 39% of pony wounds, more than half of which were located on the limb.2 Thus, a significant number of wounds must heal by second intention. Unfortunately, this type of repair leads to formation of a much larger scar tissue than that formed after successful primary closure, and function and appearance may be adversely affected.

PHASES OF WOUND REPAIR

Acute Inflammation

Inflammation prepares the wound for the subsequent reparative phases. It purges the body of alien substances and disposes of dead tissue, while the participating cellular populations liberate mediators to amplify and sustain the events that will follow. Inflammation encompasses vascular and cellular responses whose intensity is strongly correlated to the severity of trauma. The injured endothelial cell membrane releases phospholipids that are transformed into arachidonic acid and its metabolites, which mediate vascular tone and permeability as well as platelet aggregation. The first response of the damaged blood vessel is vasoconstriction, lasting 5 to 10 minutes, after which vasodilation ensues and promotes diapedesis of cells, fluid, and protein across the vessel wall into the extravascular space. Coagulated blood and aggregated platelets together form a clot within the defect that, despite providing limited strength to the wound, seals off the injury and prevents further bleeding. The clot also functions as a scaffold through the presence of a large number of binding sites on blood proteins that are recognized by special surface receptors (integrins) found on migratory inflammatory and mesenchymal cells. Activated platelets are among the earliest promoters of inflammation, via the release of potent chemoattractants and mitogens from their storage granules. These serve as signals to initiate and amplify the reparative phases of healing and are detailed later. Over time, the surface clot desiccates to form a scab that protects the wound from infection. This scab is in turn lysed by plasmin and sloughs along with dead inflammatory cells and bacteria as healing proceeds underneath. The provisional extracellular matrix (ECM) will be replaced by granulation tissue in the next phase of repair.

Leukocytes are recruited from the circulating blood pool to the site of injury by the numerous vasoactive mediators and chemoattractants supplied by the coagulation and activated complement pathways, by platelets, by mast cells, and by injured or activated mesenchymal cells.3 These signals initiate the processes of rolling, activation, tight adhesion, and finally transmigration of inflammatory cells through the microvascular endothelium. Chemoattractants additionally stimulate the release of enzymes by the activated neutrophils; these enzymes facilitate the penetration of the inflammatory cells as they migrate through vascular basement membranes. Neutrophil diapedesis is further facilitated by increased capillary permeability after the release of a spectrum of vasodilatory agents. Cellular influx begins early, and neutrophil numbers progressively increase to reach a peak 1 to 2 days after the injury. The neutrophils act as a first line of defense in contaminated wounds by destroying debris and bacteria through phagocytosis and subsequent enzymatic and oxygen-radical mechanisms. The principal degradative proteinases released by the neutrophils to rid the site of denatured ECM components are neutrophil-specific interstitial collagenase, neutrophil elastase, and cathepsin G. Neutrophil migration and phagocytosis cease when contaminating particles are cleared from the site of injury. Most cells then become entrapped within the clot, which is sloughed during later phases of repair. The neutrophils remaining within viable tissue die in a few days and are phagocytosed by the tissue macrophages or the modified wound fibroblasts. This marks the termination of the early inflammatory phase of repair. Although the neutrophils help create a favorable wound environment and serve as a source of proinflammatory cytokines, they are not essential to repair in uninfected wounds.3

The rapid increase in macrophage numbers under inflammatory conditions is predominantly caused by the emigration of monocytes from the vasculature, which then differentiate into macrophages to assist resident tissue macrophages at the wound site for a period lasting from days to weeks. In this manner, the responsive and adaptable pluripotent monocytes can differentiate into macrophages, whose functional properties are determined by the conditions they encounter at the site of mobilization. Like the neutrophils, the macrophages are phagocytes and thus carry out debridement and microbial killing. Unlike the neutrophils, the wound macrophages play a key role in the reparative phases of healing. Indeed, adherence to the ECM (which consists of a cross-linked supporting framework of collagen fibrils and elastin fibers, which is saturated with proteoglycans and other glycoproteins) stimulates monocytes to transform into phenotypes that have the ability to

![Figure 5-1. Temporal profile of various processes and gain in tensile strength occurring during normal cutaneous wound repair.](image)
continually synthesize and express the various cytokines necessary for their survival, as well as for the initiation and propagation of new tissue formation in wounds (Fig. 5-2). A classic series of experiments in the 1970s determined that wounds depleted of both circulating blood monocytes and tissue macrophages exhibited not only severe retardation of tissue débridement but also a marked delay in fibroblast proliferation and subsequent wound fibrosis. Although it has long been considered that the inflammatory response is instrumental in supplying cytokine and growth factor signals that orchestrate the cell and tissue movements necessary for repair, it has recently been shown that mice genetically lacking macrophages and functioning neutrophils are able to repair skin wounds within a time frame similar to that seen in their wild-type siblings, and these repairs appear scar free, possibly in response to an altered local cytokine and growth factor profile.

On arrival at the site of inflammation, macrophages participate in bacterial killing via mechanisms that parallel those of the neutrophils. Three inducible, secreted, neutral proteinases have been identified in macrophages: elastase, collagenase, and plasminogen activator (PA). These proteinases aid in degradation of damaged tissue and debris, which must be cleared before repair can proceed. Despite the new data gleaned from the study on mice without macrophages, acute inflammation is still considered crucial to the normal outcome of wound repair. Indeed, macrophages are regarded as the major inflammatory cell responsible not only for débridement but also for recruitment of other inflammatory and mesenchymal cells, and for subsequent induction of angiogenesis, fibroplasia, and epithelialization. Thus, a general approach for improving wound repair may be to recruit or possibly activate monocytes. For example, it has recently been shown that priming a planned incision site with recombinant proinflammatory cytokines nearly doubles the breaking strength of an acute wound. Likewise, honey and sugar (Intracell, Macleod Pharmaceutical, Ft. Collins, Colo.) applied to open wounds have been shown to enhance fibroplasia and epithelialization, possibly via their chemoattractant and stimulatory activity on the tissue macrophages. A β-(1-4)-acetylated mannan, available as a topical hydrogel (Carravet, Veterinary Products Laboratories, Phoenix, Ariz.; Carrasorb, Carrington Laboratories, Irving, Tex.), likewise enhances the early stages of wound repair by stimulating macrophages to produce proinflammatory cytokines.

Paradoxically, prolonged inflammation retards healing and encourages the development of chronic proliferation of fibroblastic granulation. This is thought to contribute to the pathogenesis of a number of diseases characterized by disproportionate scarring, such as pulmonary fibrosis, hepatic cirrhosis, glomerulonephritis, and dermal keloids in humans. Extensive scarring or fibrosis of any organ may cause catastrophic loss of function of that organ. In the horse, a comparable condition is the development of exuberant granulation tissue in skin wounds (Fig. 5-3). Wilmink and colleagues believe this is related to a deficient but protracted inflammatory response in the horse when compared with ponies, especially when wounds are located at the distal aspect of the limb. They found that the number of polymorphonuclear leukocytes (PMNs) was high in ponies during the first 3 weeks after experimental full-

Figure 5-2. Cutaneous wound 3 days after injury. bFGF, basic fibroblast growth factor; IGF, insulin-like growth factor; KGF, keratinocyte growth factor; PDGF, platelet-derived growth factor; TGF, transforming growth factor; VEGF, vascular endothelial growth factor. tissue in equine lower limb wounds. The active ingredient efficacy of Vulketan gel (Janssen Animal Health, Beerse, a field study was recently performed to determine thetracted inflammation and delaying epithelialization. Finally, wounds. Subsequently, it inhibited repair by causing pro-
voked a greater inflammatory response, with faster forma-
(tion subsides and is characterized by the eventual appearance of red, fleshy granulation tissue, which ultimately fills the defect. Although the earliest part of this phase is very active at the cellular level, this does not immediate translate into a gain in wound strength. Indeed, during the first 3 to 5 days after injury, mesenchymal cells such as fibroblasts and endothelial and epithelial cells are rapidly invading the wound in preparation for matrix syn-
thesis and maturation; however, these latter reinforcing mechanisms lag somewhat. Granulation tissue is formed by three elements that move into the wound space simultaneously: macrophages débride and produce cytokines and growth factors released by inflammatory cells, are believed to stimulate fibroblasts from adjacent uninjured skin to prolifera-
tion and express integrin receptors to assist migration

thickness wounding, but it subsequently decreased rapidly, whereas in the horse the initial number of PMNs was lower, but it remained persistently elevated during the entire 6-week study. Furthermore, peripheral blood leukocytes from ponies produce more reactive oxygen species essential to bacterial killing than do those of horses, which corresponds to the more pronounced initial inflammatory response and to the better local defense against wound infection clinically apparent in the pony.

A handful of equine studies have been undertaken with the intent of encouraging a powerful yet brief acute inflammatory response and thus limiting the subsequent fibrosis that appears in response to injury to the distal portion of the limb in horses. Wilson and colleagues found that although an activated macrophage supernate effectively restrained proliferation of equine fibroblasts in vitro, no significant in vivo effects were found on distal limb wounds. Another study found that a protein-free dialysate of calf blood (Solcoseryl, Solco Basle Ltd., Birsfelden, Switzerland) provoked a greater inflammatory response, with faster formation and contraction of granulation tissue within deep wounds. Subsequently, it inhibited repair by causing protracted inflammation and delaying epithelialization. Finally, a field study was recently performed to determine the efficacy of Vulketan gel (Janssen Animal Health, Beerse, Belgium) in preventing exuberant formation of granulation tissue in equine lower limb wounds. The active ingredient appears to antagonize serotonin-induced suppression of wound macrophages, thus allowing a strong, effective inflammatory response to occur. Vulketan was two to five times more likely to result in successful closure by reducing

infection and proud flesh formation, than an antiseptic or a dislodging agent.

Inflammation is a sequence of events: production of mediators; rolling, tethering, and adhesion of neutrophils to vascular endothelium, with subsequent migration through endothelium and basement membranes; altered vascular permeability with passage of fluid into tissues; neutrophil phagocytosis of invading organisms, and release of biolog-
ically active materials; emigration of monocytes from the local vasculature; and maturation of monocytes into inflammatory macrophages with subsequent removal of the components of inflammation. Resolution of inflammation should therefore address each one of these events and halt or potentially reverse it. However, despite the importance of the processes by which inflammation normally resolves, little research has been done in this area.

Apoptosis, or programmed cell death, is the universal pathway for the elimination of unneeded cells and tissues in a phagocytic process that does not elicit additional inflammation. This mechanism is prevalent during all phases of wound repair, as each phase relies on rapid increases in specific cell populations that either prepare the wound for repair (inflammatory cells) or deposit new matrices and mature the wound (mesenchymal cells), but the cell populations must then be eliminated prior to progression to the next phase. Indeed, a mature wound is typically acellular.

In conclusion, the termination of inflammation is a complex but closely regulated sequence of events. There are several steps at which the resolution process could go astray, leading to suppuration, chronic inflammation, and/or excessive fibrosis.

**Cellular Proliferation**

**Fibroplasia**

The proliferative phase of repair comes about as inflam-
mation subsides and is characterized by the eventual appearance of red, fleshy granulation tissue, which ultimately fills the defect. Although the earliest part of this phase is very active at the cellular level, this does not immediately translate into a gain in wound strength. Indeed, during the first 3 to 5 days after injury, mesenchymal cells such as fibroblasts and endothelial and epithelial cells are rapidly invading the wound in preparation for matrix synthesis and maturation; however, these latter reinforcing mechanisms lag somewhat. Granulation tissue is formed by three elements that move into the wound space simultaneously: macrophages débride and produce cytokines and growth factors, which stimulate angiogenesis and fibroplasia (see Fig. 5-2); fibroblasts proliferate and synthesize new ECM components; and new blood vessels carry oxygen and nutrients necessary for the metabolism and growth of mesenchymal cells, and confer to the granulation tissue its characteristic appearance. This stroma, of which fibronectin and hyaluronan are major components, replaces the fibrin-containing clot to provide a physical barrier to infection and, importantly, to proffer a surface across which mesenchymal cells can then migrate. A number of matrix molecules, as well as chemoattractants, cytokines, and growth factors released by inflammatory cells, are believed to stimulate fibroblasts from adjacent uninjured skin to prolifera-
into the wound space. Integrins are transmembrane proteins that act as the major cell-surface receptors for ECM molecules and thus mediate interactions and transduce signals between cells and their environment. They are particularly critical to the migratory movements exhibited by wound-healing cells. Migration immediately precedes advancing capillary endothelial buds but follows macrophages, which have cleared a path by phagocytosing debris. Fibroblasts themselves also possess an active proteolytic system to aid migration into the cross-linked fibrin blood clot; proteinases include PA, various collagenases, gelatinase, and stromelysin.18

Once fibroblasts have arrived within the wound space, they proliferate and then switch their major function to protein synthesis and commence the gradual replacement of provisional matrix by a collagenous one, probably under the influence of various cytokines and growth factors. As the wound matures, there is a marked increase in the ratio of type I (mature) to type III (immature) collagen; proteoglycans also become abundant within the mature matrix. The greatest rate of connective tissue accumulation within the wound occurs 7 to 14 days after injury, and thus this is the period with most rapid gain in tensile strength (see Fig. 5-1). Thereafter, collagen content levels off as fibroblasts retract their synthetic machinery; this corresponds to a much slower gain in wound strength, which occurs as the wound remodels. The fibroblast-rich granulation tissue is then replaced by a relatively avascular and acellular scar as the capillary content regresses and fibroblasts either undergo apoptosis17 or acquire smooth-muscle characteristics and transform into myofibroblasts that participate in wound contraction. The latter phenomena are regulated by the physiologic needs and/or the microenvironmental stimuli present at the wound site. It appears that if the signal to downregulate fibroblast activity is delayed beyond a specific time point, apoptosis is permanently impaired, which ultimately leads to an imbalance between collagen synthesis and degradation17 and the formation of excessive scar tissue, such as that seen in human keloids.18

Following this logic, and since the horse activates wound collagen formation to a greater extent and at an earlier time during repair than do other species,19 it is hypothesized that excessive fibrosis in the horse may relate to an imbalance between collagen synthesis and lysis in favor of the former, possibly as a result of deficient fibroblast apoptosis. Undeniably, repair of full-thickness wounds in the horse is subject to excessive formation of granulation tissue, with subsequent delays in epithelialization and contraction, especially when wounds are located at the distal aspect of the limb.20 Predilection for this site remains unexplained, but it may result from a population of dermal fibroblasts possessing particular morphologic and functional characteristics, or it may relate to the local environment of the wound. Surprisingly, in vitro fibroblast growth from tissues isolated from the horse limb is significantly less rapid than growth of fibroblasts from the horse trunk.21 In vivo, an elevated and persistent mitotic activity exists in distal growth of fibroblasts from the horse trunk.21 In vivo, an elevated and persistent mitotic activity exists in distal growth of fibroblasts from the horse trunk.21 In vivo, an elevated and persistent mitotic activity exists in distal growth of fibroblasts from the horse trunk.21 In vivo, an elevated and persistent mitotic activity exists in distal growth of fibroblasts from the horse trunk.21

This resembles the different mitotic activities of fibroblasts from various sites in the rat where regional differences in granulation tissue formation also exist,22 and it may indicate deficient cell death, which could result from downregulation of apoptosis-related genes, as occurs in humans.23 We recently investigated this hypothesis in the horse and found that the balance of apoptotic signals was altered against apoptosis in limb versus body wounds.24

Silicone dressings are used for the prevention of excessive fibroplasia and scarring in man. It appears that this type of synthetic, nonadherent, and fully occlusive dressing surpasses other modalities for decreasing the amount of scar tissue while exerting no negative side effects. In a recent study performed in wounds of the distal limbs of horses, we found that the silicone dressing surpassed a conventional permeable, nonadherent dressing for preventing the formation of exuberant granulation tissue and improving tissue quality.25

**Angiogenesis**

Besides initiating the inflammatory response through interaction with leukocytes, microvascular endothelial cells play a key role in the proliferative phase of repair. The formation of new capillary blood vessels from preexisting ones (angiogenesis) is necessary to sustain the granulation tissue newly formed within the wound bed. Angiogenesis, in response to tissue injury and hypoxia, is a complex and dynamic process mediated by diverse soluble factors from both serum and the surrounding ECM environment—in particular, angiogenic inducers including growth factors, chemokines, angiogenic enzymes, endothelial cell–specific receptors, and adhesion molecules26 (see Fig. 5-2), many of which are released during the previous inflammatory phase of repair.

Construction of a vascular network requires sequential steps that include augmented microvascular permeability, the release of proteinases from activated endothelial cells with subsequent local degradation of the basement membrane surrounding the existing vessel, migration and sprouting of endothelial cells into the interstitial space, endothelial cell proliferation and formation of granulation tissue, differentiation into mature blood vessels, and stabilization, eventually followed by regression and involution of the newly formed vasculature as the tissue remodels.27 Angiogenesis depends not only on the cells and cytokines present but also on the production and organization of ECM components, which act both as scaffold support through which endothelial cells may migrate, and as reservoir and modulator for growth factors. Thus, endothelial cells at the tips of capillaries begin their migration into the wound in response to angiogenic stimuli and absence of neighboring cells, on the second day following injury. Cytoplasmic pseudopodia extend through fragmented basement membranes; subsequently, the entire cell migrates into the perivascular space. Cells remaining in the parent vessel near the tip of the angiogenic sprouts begin to proliferate, providing a continuous source of microvascular endothelial cells for angiogenesis. When a new capillary sprout first develops, it is solid; after it fuses with a neighboring sprout to form an arcade it becomes canalized and erythrocytes pass into and through it. Lumen formation probably involves the joining of plasma membranes of individual or adjacent cells, as well as extensive intracellular vacuolization followed by fusion of the vacuoles to form ring cells, which
ultimately fuse to form seamless capillaries. Capillaries are then stabilized by endothelial cells and interact with the new basement membrane within 24 hours of new vessel formation. Once the reconstitution of parenchyma is complete, there is no longer the need for a rich vascular supply. Angiogenic stimuli are downregulated or the local concentration of inhibitors increases and most of the recently formed capillary network quickly involutes through the activity of matrix metalloproteinases (MMPs)\(^{28}\) and apoptosis of endothelial cells. The wound color becomes correspondingly paler as the rich capillary bed disappears from the granulation tissue.

Exuberant granulation tissue that develops in wounds of the lower limbs of horses is characterized microscopically by a great number of microvessels. Although the reason angiogenesis is more prominent in this location remains obscure, it is tempting to speculate that the regional paucity of blood supply may impart an effect via upregulation of various angiogenic factors. Indeed, hypoxia is known to obscure, it is tempting to speculate that the regional paucity of blood supply may impart an effect via upregulation of various angiogenic factors. Indeed, hypoxia is known to stimulate proliferation and synthetic activity of fibroblasts.\(^{29}\)

In support of this hypothesis, we have recently shown that although a greater number of microvessels are microscopically apparent within the granulation tissue of limb wounds in horses, their lumens are occluded significantly more often than the lumens of microvessels within thoracic wounds, which may corroborate the existence of a hypoxic environment in wounds of the lower limb.\(^{24}\) Thus, via upregulation of various angiogenic factors, hypoxia may lead to excessive fibrosis. Alternatively, deficient apoptotic signals may lead to persistence of microcapillary endothelial cells and subsequent angiogenic activity.

**Epithelialization**

All body surfaces are covered by epithelium, which acts as a selective barrier to the environment. Epithelium provides the primary defense against hostile surroundings and is a major factor in maintaining internal homeostasis by limiting fluid and electrolyte loss. The outer region of skin, a multilayered stratified squamous epithelium (the epidermis), interfaces with the musculoskeletal framework by means of a connective tissue layer (the dermis) and a fibrofatty layer (the subcutis). Epidermis is attached to the dermis at the level of the basement membrane, a thin, glycoprotein-rich layer composed primarily of laminin and type IV collagen. This attachment is mediated by hemidesmosomes, which physically attach the basal cells of the epidermis to the underlying dermis, as well as by vertically oriented type VII collagen anchoring fibrils, which bind the cytoskeleton.\(^{30}\)

It is critical to survival that an epidermal wound be covered without delay. In addition to the aforementioned hemostatic activities, which establish a temporary barrier, centripetal movement of the residual epithelium below the clot participates in wound closure. Although epithelial migration commences 24 to 48 hours after wounding, the characteristic pink rim of new epithelium is not microscopically visible until 4 to 6 days later, although this is variable because the rate of wound closure depends on the animal species as well as on the wound site, substrate, and size. For example, epithelialization is accelerated in a partial-thickness wound, because migrating cells arise not only from the residual epithelium at the wound periphery but also from remaining epidermal appendages. Furthermore, the basement membrane is intact in this type of injury, precluding its lengthy regeneration. On the other hand, during second-intention healing of a full-thickness wound, epithelialization must await the formation of a bed of granulation tissue to proceed. Wounds in the flank area of a horse epithelialize at a rate of 0.2 mm per day, compared with a rate as slow as 0.09 mm per day for wounds in the distal portion of limbs.\(^{31}\)

In preparation for migration, basal epidermal cells at the wound margin undergo phenotypic alterations that favor mobility and phagocytic activity. Additionally, various degradative enzymes necessary for the proteolysis of ECM components are upregulated within cells at the leading edge, facilitating ingestion of the clot and debris found along the migratory route. The migratory route is determined by the array of integrin receptors expressed on the surface of migrating epithelial cells, for various ECM proteins. Indeed, a fundamental reason why migrating epidermis dissects the fibrin eschar from wounds is that normal epithelial cells cannot interact with the fibrinogen and its derivatives found within the clot because they lack the appropriate integrin.\(^{32}\)

Once the wound surface is covered by epithelial cells that contact one another, further migration from the margin of the wound inward is inhibited by the expression within the ECM of laminin, a major cell adhesion factor for epithelial cells.

Although initial migration does not require an increase in cellular multiplication, epidermal cells at the wound margin do begin to proliferate 1 to 2 days after injury to replenish the migratory front. This corresponds histologically to epithelial hyperplasia (Fig. 5-4), as cellular mitosis increases 17-fold within 48 to 72 hours. The new cells leapfrog over those at the wound margin to adhere to the substratum, only to be replaced in turn by other cells coming from above.
Collagen may function as a substrate for hemostasis; as a
and are appraised as improving rate and quality of repair.
As collagen membranes and sponges have been developed
wounds during the proliferative phase, biomaterials such
soluble epithelial cell–derived product, possibly a cytokine
proliferation and collagen synthesis may be regulated by a
regions). The inhibitory effect of grafts on fibroblast pro-
(t.e., from the lateral cervical, abdominal, or pectoral
heals well and in which contraction is a prominent feature
proliferation and migration of epithelial cells. It is, however,
contract process. A commercially available collagen
significantly alter the total wound, or the epithelialization or
growth factor content of wound tissues, although it did not
limb wounds of horses, which may augment the cytokine or
growth factor of wound tissues, although it did not
significantly alter the total wound, or the epithelialization or
contraction process. A commercially available collagen
matrix derived from porcine small intestinal submucosa
(Vet BioSIS, Cook Veterinary Products, Inc, Spencer, Ind.)
and containing a plethora of proteins and growth factors,
have been designed as a scaffold for tissue ingrowth and is
promoted as reducing scarring. Regrettably, a recent study
determined that it offers no apparent advantage over a
nonbiologic, nonadherent synthetic dressing for treatment
of small, granulating wounds of the distal limb of horses.

Matrix Synthesis and Remodeling
In addition to epithelialization, contraction contributes to
the successful closure of full-thickness wounds. Contraction
is defined as a process whereby both dermis and epidermis
bordering a full-thickness skin defect are drawn from all
sides centripetally over the exposed wound bed. This
occurs usually during the second week after injury. Wound
contraction not only accelerates closure but also enhances
the cosmetic appearance and strength of the scar, because
proportionally less wound area must be covered by newly
formed, inferior quality epithelium, which is fragile and
lacks normal nervous, glandular, follicular, and vascular
components. For this reason, a high degree of wound
contraction is a desired feature of wound repair, at least in
the horse.

A number of theories have been proposed to explain
wound contraction, but most authorities agree that it
involves a finely orchestrated interaction of ECM, cytokines
or growth factors, and cells—in particular, a specialized fibro-
blast phenotype, the myofibroblast (Fig. 5-5). Myofibroblasts

Figure 5-5. Transmission electron micrograph showing a typical
myofibroblast with microfilament bundles illustrated in the inset
(arrows). Bar = 1 µm.
WOUND REPAIR

are the most abundant cellular elements of healthy granulation tissue and are aligned within the wound along the lines of contraction, in contrast to capillaries and macrophages. The most striking feature of the myofibroblasts is a well-developed alpha smooth muscle actin (α-SMA) microfilamentous system, arranged parallel to the cell’s long axis and in continuity with ECM components via various integrins. In addition to these cell-substratum links, intercellular connections such as gap junctions and hemidesmosomes ensure that neighboring cells exert tension on one another. Factors producing and regulating contraction are presently unknown, but they appear to include various cytokines and growth factors.

Wound contraction is divided into three phases. An initial lag phase (wherein skin edges retract and the wound area increases temporarily for 5 to 10 days) occurs because significant fibroblastic invasion into the wound is a prerequisite for contraction. Subsequently, a period of rapid contraction is followed by a period of slow contraction as the wound approaches complete closure. The number of myofibroblasts found in a wound appears to be proportional to the need for contraction; thus, as repair progresses and the rate of contraction slows, this number decreases. During wound contraction, the surrounding skin stretches by intussusceptive growth, and the wound takes on a stellate appearance. Contraction ceases in response to one of three events: the wound edges meet and contact inhibition halts the processes of both epithelialization and contraction; tension in the surrounding skin becomes equal to or greater than the contractile force generated by the α-SMA of the myofibroblasts; or, in the case of chronic wounds, a low myofibroblast count in the granulation tissue may result in failure of wound contraction despite laxity in the surrounding skin. In this case, the granulation tissue is pale and consists primarily of collagen and ground substance. Wound contraction is greater in regions of the body with loose skin than in regions where skin is under tension, such as the distal aspect of the limb in the horse. Although it has been speculated that the shape of the wound may influence the process of contraction, this does not appear relevant in wounds at the distal extremities of horse limbs where skin is tightly stretched and not easily moved. Skin grafts have been reported to inhibit contraction by preventing formation of myofibroblasts or by accelerating the myofibroblast life cycle, although this is questionable in the horse.

As contraction concludes, myofibroblasts disappear, either by reverting to a quiescent fibroblast phenotype or by apoptosis, primarily in response to reduced tension within the ECM. The myofibroblast persists in fibrotic lesions, where it may be involved in further ECM accumulation and pathologic contraction, a condition rarely encountered in the horse, but leading to significant morbidity particularly when it involves joints or body orifices.

Significant differences exist with regard to contraction between horses and ponies and between distinct areas of the body. Wound contraction is clearly more pronounced in ponies than in horses, and the rate of contraction of limb wounds is at best 25% that of flank wounds. A study reported no difference in the amount of α-SMA in distal metatarsal versus buttocks wounds in horses, but it described a disorganized arrangement of myofibroblasts in chronic wounds of the distal limb. This particular arrangement may be related to fibronectin being scarce between myofibroblasts of the granulation tissue, and it could be responsible for deficient contractile activity within the wounds. Contrary to expectations, it was shown that fibroblasts harvested from the limb do not display a slower rate of contraction than do those harvested from the body, at least in vitro. Rather, it appears that tissue environmental factors emanating from the inflammatory response to injury, such as cytokine or growth factor profiles, are instrumental in causing this difference.

The conversion of ECM from granulation to scar tissue constitutes the final phase of wound repair and consists of connective tissue synthesis, lysis, and remodeling, also referred to as maturation. Proteoglycans replace hyaluronan during the second week of repair, support the deposition and aggregation of collagen fibers, and provide the mature matrix with greater resilience. Collagen macromolecules provide the wound tissue with tensile strength as their deposition peaks within the first week in primary wound repair, and between 7 and 14 days in second-intention healing. Although this corresponds to the period of most rapid gain in strength, only 20% of the final strength of the wound is achieved in the first 3 weeks of repair. At this time, collagen synthesis is balanced by collagenolysis, which normally prevents accretion of excessive amounts of collagen and formation of pathologic scars. It appears that during the development of exuberant granulation tissue in horses, collagen synthesis continues unabated. The balance between synthesis and degradation determines the overall strength of a healing wound at a particular time. The first newly deposited collagen tends to be oriented randomly and therefore provides little tensile strength, whereas during remodeling the fibers re-form along lines of stress and therefore resist dehiscence more effectively. Crosslinking in the later-formed collagen is also more effective, although never to the same extent as in the original tissue. A recent study has shown that newly accumulated collagen fibrils are disorganized in wounds at the distal aspect of the forelimb of horses but more normally organized in thoracic wounds. The new collagen weaves into the collagen that preexisted and also appears to bond to the ends of old collagen fibers. These welds are points of weakness that may rupture under stress.

Because the ultimate tensile strength of a wound is related to collagen content, therapies that favor its synthesis and deposition are continuously sought. Growth hormone is postulated to stimulate collagen synthesis through fibroblasts and accelerate its maturation, resulting in enhanced wound strength, effects that are probably mediated through various growth factors. Regrettably, a study investigating the effect of intramuscular injections of recombinant equine growth hormone on maturation of limb wounds in horses found that the wounds contracted at a faster rate only after treatment ended.

Collagen degradation within a wound depends on the presence of various proteolytic enzymes released from inflammatory and mesenchymal cells. Most are of the MMP family of zinc-dependent endopeptidases that are collectively capable of degrading virtually all ECM components. Although MMPs are not constitutively expressed in skin,
upregulation occurs whenever proteolysis is required, such as during cell migration and matrix remodeling. Inactive precursors (zymogens) of the MMPs are cleaved in the extracellular space by proteinases such as plasmin and trypsin (left over from the inflammatory and proliferative phases) and also by other MMPs. To date, a dozen different MMPs, all distinct gene products, have been characterized (Table 5-1). The best-known subgroup of MMPs are the collagenases (MMP-1, 8, and 13), which possess the unique ability to cleave the triple helix of native types I, II, and III collagens, the rate-limiting step of collagen degradation. The fragments generated are thermally unstable and denature into their constituent polypeptide chains, forming gelatin peptides. Basal epithelial cells at the migratory front of epithelialization are the predominant source of collagenase during active wound repair, whereas the resolution of granulation tissue also depends on the activity of collagenase, in this case expressed by dermal fibroblasts. Another subgroup of MMPs, the stromelysins, possess a broad substrate specificity. Stromelysin-1 and -2 are strong proteoglycanases and can also degrade basement membranes, laminin, and fibronectin, whereas stromelysin-3 is only weakly proteolytic. Although stromelysin-2 expression is strictly confined to the epidermis, stromelysin-1 is also abundantly expressed by dermal fibroblasts in the granulation tissue associated with wounds, and because of its broad substrate specificity, it may be important in remodeling the matrix—in particular, the newly formed basement membrane—during repair. There are two metalloelastinases: the 72-kDa gelatinase (gelatinase A), which, unlike other MMPs, is produced constitutively by most cell types, and the 92-kDa gelatinase (gelatinase B), produced by most inflammatory cells as well as by epithelial cells. Both types efficiently degrade denatured collagens (gelatins) and also attack basement membranes, fibronectin, and insoluble elastin. Matrilysin is the smallest MMP (28 kDa), but it is a stronger proteoglycanase than stromelysin and also degrades basement membranes, insoluble elastin, laminin, fibronectin, and gelatin.

Homeostasis between collagen synthesis and degradation during the remodeling phase depends on the simultaneous presence of MMPs and nonspecific inhibitors such as α2-macroglobulin and α1-antiprotease, as well as the natural specific inhibitors of MMPs, the TIMPs. TIMPs are a gene family of four structurally related members, TIMP-1 through -4, that inhibit conversion of MMPs from a zymogen to an activated state and that irreversibly bind to the catalytic site of active MMPs. The role of TIMPs in wound repair is not limited to remodeling, as they also promote growth in a wide range of cell types, and they are thought to stabilize the basement membrane of regenerating epidermis and to inhibit angiogenesis and induce apoptosis.

Inhibition of MMP activity during the acute inflammatory phase of repair enhances wound strength despite accompanying decreases in the inflammatory response and new collagen synthesis. This is thought to result from decreased collagen turnover or increased collagen maturation and crosslinking, or both. However, under most circumstances, an imbalance between MMPs and TIMPs leads to abnormal resolution and delayed repair. Indeed,

</table>
although the presence of MMPs is essential for normal wound maturation, it may also be responsible for the inability of chronic wounds to heal. For example, chronic wound fluid is characterized by elevated levels of proteinases, particularly MMP-9 and serine proteinases, which lead to excessive protein degradation and the inactivation of critical growth factors. Chronic wounds also contain reduced levels of TIMPs—in particular, TIMP-1.49 It is interesting that as epithelialization progresses, the production of MMPs by epithelial cells is turned off, allowing the formation of hemidesmosomal adhesions between cells and the basement membrane.

Schwartz and coworkers recently documented greater collagen synthesis in metacarpal than thoracic wounds of horses and attributed this to an imbalance between collagen synthesis and degradation.46 Although TIMP-1 expression was significantly higher in forelimb than in thoracic wounds at 1 week after the wounding, which may imply that collagen degradation is inhibited at this time, the relationship between concentrations of MMP-1 and TIMP-1 throughout the course of the study was unclear.46

Wound remodeling continues for up to 2 years, during which time there is no net increase in collagen content—rather, a rearrangement of collagen fibers into a more organized lattice structure, under the influence of local mechanical factors, progressively increasing the tensile strength of scar tissue. The majority of type III collagen fibers laid down early in the healing process are replaced by collagen type I, the fibers become increasingly cross-linked, and the normal skin ratio of 4:1 type I to type III collagen is achieved. Glycosaminoglycans are steadily degraded until they reach concentrations found in normal dermis. The duration of the maturation phase depends on a variety of factors including the patient’s genetic makeup, age, location of the wound on the body, type of injury, and duration of inflammation. At maximum strength, cutaneous wounds remain 15% to 20% weaker than the normal surrounding tissue, although this varies markedly among species50 (see Fig. 5-1).

MEDIATORS OF WOUND REPAIR: CYTOKINES AND GROWTH FACTORS

Wound repair relies on a complex amalgamation of interactive processes involving formed blood elements, ECM, and mesenchymal cells. Although histologic and morphometric observations have permitted a detailed description of the kinetics of cellular and macromolecular components involved in repair, much remains to be learned about the regulation of such activities. Restoration of structural integrity and partial functional properties appear to rely on soluble mediators synthesized by cells, present in the wound or in the surrounding tissue, that form a dense communication network that coordinates migration, proliferation, and protein synthesis by the various cell populations involved in the repair process.

Cytokines, defined as 4- to 60-kDa signaling glycoproteins released by most nucleated cells, are among the most important soluble mediators regulating wound repair. They act in concentrations of 10^6 to 10^12 M in an autocrine (same-cell), paracrine (adjacent-cell), or endocrine (distant-cell) fashion. For cytokines to exert an effect, the target cell must express a surface receptor to the specific mediator. Receptors are proteins with an extracellular site to bind the cytokine and a transmembrane site to transmit the signal to the intracellular site, where it must reach nuclear DNA for a specific response to occur. Cells may have different numbers of receptors for different factors; the concentration of factors in the area and the number of receptors that are bound determine the response generated. Growth factors are cytokines, which exert primarily mitogenic influences. The cytokines that play a significant role in cutaneous wound repair are summarized in Table 5-2.

Colony-Stimulating Factors

Four cytokines classified as colony-stimulating factors (CSFs) have been identified: granulocyte (G) CSF, macrophage (M) CSF, granulocyte-macrophage (GM) CSF, and multilineage (ML) CSF.51 Many cells involved in repair, including macrophages, lymphocytes, fibroblasts, and endothelial cells, synthesize CSFs or are targets of this cytokine.52 Indeed, the way in which CSFs influence repair is by promoting the differentiation and maturation of hematopoietic stem cells to progenitor cells and, finally, to granulocytes, monocytes, macrophages, and lymphocytes. These mature cells can, in turn, secrete or produce secondary cytokines with subsequent effects on inflammation, angiogenesis, epithelialization, and fibroplasia. Cloning of equine GM-CSF has recently been achieved.53

Interferons

Interferons (IFNs) represent a family of cytokines originally discovered because of their antiviral activity, but they also influence general immunity, activating and modulating lymphocytes, macrophages, and natural killer and dendritic cells.54 Type I IFNs share the same ubiquitously expressed receptor, and they include IFN-α, produced by dendritic cells and monocytes/macrophages, and IFN-β, produced by several mesenchymal cell types. Interferon-γ is a type II IFN with its own distinct and more specifically expressed receptor, and they include IFN-α, produced by dendritic cells and monocytes/macrophages, and IFN-β, produced by several mesenchymal cell types. Interferon-γ is a type II IFN with its own distinct and more specifically expressed receptor. In horses, IFN-α1, -β, and -γ were cloned and sequenced earlier,55 but recombinant proteins allowing the analysis of protein, antibodies, and biologic activity became available only recently.56 Interestingly, it was revealed that although recombinant equine IFN-γ does not display substantial antiviral activity, it does show immunomodulatory effects on monocytes, at least in vitro. This indicates that IFN-γ may stimulate the inflammatory phase of repair, via release by activated monocytes and macrophages of a plethora of additional cytokines, in particular interleukins (ILs) and growth factors. Interestingly, IFN-γ is thought to prevent excessive fibrosis from occurring in the later stages of repair, which may be of particular significance to wound healing in the horse.57

Interleukins

Interleukins are produced by virtually every nucleated cell (in particular, macrophages and lymphocytes) and most cells express IL surface receptors through which the cytokine mediates cell-to-cell and cell-to-matrix interactions. Two different IL-1 peptides with diverging isoelectric focusing points exist: IL-1α and IL-1β. There is very close homology
between the two, and both activate cells and stimulate their proliferation. Interleukin-1 has a wide range of biologic activities, many of which are proinflammatory, but it also aids in the later phases of repair. Notably, IL-1 is synthesized by epithelial cells in response to injury and favors epithelialization by directly stimulating chemotraction of epithelial cells, and by indirectly enhancing their proliferation by upregulating keratinocyte growth factor (KGF) production by wound fibroblasts. The autocrine nature of epithelial cell–derived IL-1 is emphasized by the fact that it additionally induces the cell to synthesize IL-1, transforming growth factor (TGF)-α, and KGF. Interleukin-1 also influences matrix synthesis and remodeling via stimulation of fibroblast proliferation and enhancement of collagenase production. Circular DNAs (cDNAs) for equine IL-1α and IL-1β,58 as well as for their natural inhibitor, IL-1 receptor antagonist (IL-1ra), have been cloned, sequenced, and expressed.59

Other ILs have also been attributed a role in wound repair. For example, it has been shown, with the help of IL-6–deficient mice, that repair of excisional wounds requires this particular IL to proceed normally via gene expression of IL-1, chemokines, adhesion molecules, TGF-β1, and vascular endothelial growth factor (VEGF).60,61 Interleukin-8 appears to accelerate maturation of granulation tissue, encouraging the formation of thicker, more mature collagen fibers.62 On the other hand, IL-10 seems inhibitory to ECM remodeling during wound repair, reducing tumor necrosis factor (TNF)-α–induced fibroblast proliferation, decreasing concentrations of TGF-β1, and inhibiting collagen type I protein synthesis by dermal fibroblasts, at least in vitro.63

### Tumor Necrosis Factor-α

TNF-α is produced by a variety of cell types, including macrophages, T cells, mast cells, and epithelial cells, and...
exerts principally inflammatory effects, TNF-α may favor angiogenesis through chemoattraction and proliferation of endothelial cells, and it is also thought to enhance remodeling through fibroblast proliferation and up-regulation of collagen as well as TIMP-1 levels.66 Finally, TNF-α has also been shown to stimulate epithelial cell migration. The gene encoding equine TNF-α has been cloned and characterized.64

Growth Factors

Connective Tissue Growth Factor

Connective tissue growth factor (CTGF) is a heparin-binding peptide whose secretion by fibroblasts is selectively induced by TGF-β and whose biologic activities resemble those of platelet-derived growth factor (PDGF).65 CTGF acts in an autocrine and paracrine fashion on connective tissue cells, in particular the fibroblast, in which it mediates TGF-β activity as a downstream effector and thus indirectly stimulates cell proliferation and ECM accumulation.65 Connective tissue growth factor expression in blood vessels suggests that this growth factor is also involved in angiogenesis. Thus, CTGF is an interesting target for future antifibrotic therapies, as it is conceivable that its inhibition may block the profibrotic effects of TGF-β without affecting the antiproliferative and immunosuppressive effects of TGF-β.66 Although equine CTGF has not been cloned, an antigenic similarity between human and horse CTGF was recently established in a bioequivalence assay.66 Interestingly, this same study demonstrated that fibrogenic CTGF is present in horse lacrimal fluid and derives, at least partly, from the lacrimal gland. This may explain why repair of corneal ulcers in horses is often associated with profound corneal stromal fibrosis and scar formation.

Epidermal Growth Factor and Transforming Growth Factor-α

Although plasma levels of EGF are undetectable, platelets release substantial amounts on aggregation. This growth factor is also abundant in saliva, which may represent the physiologic basis for wound licking. As its name would imply, EGF enhances epithelialization through various mechanisms: accrued contractility of epithelial cells allows more efficient migration,69 and both proliferation and differentiation are favored. Furthermore, EGF exerts positive effects on the wound fibroblast, including chemoattraction, mitogenesis, and up-regulation of protein and MMP synthesis, important to the remodeling phase of repair.32 The coding sequence for equine EGF has been identified and it shows 60% to 70% amino acid identity with EGF sequences of other species.30

TGF-α, which has no amino acid homology with TGF-β, is synthesized by activated macrophages and epithelial cells, and although it is distinct from EGF, it binds to the same cell-surface receptor and exhibits similar biologic activities. Like EGF, it is a chemoattractant and mitogen for epithelial cells and fibroblasts; however, it is considered a more potent inducer of angiogenesis, in particular via initiation of tube formation by microvascular endothelial cells.75 Interestingly, TGF-α has also been attributed a role in host defense during wound repair, by inducing the expression of antimicrobial peptides in proliferating epithelial cells, which complement the physical barrier against microorganisms formed by new epithelium.72

Fibroblast Growth Factor

Basic fibroblast growth factor (bFGF), also called heparin-binding growth factor-2, is the most extensively studied member of a growing group of structurally related proteins having high affinity for heparin, and it was one of the first angiogenic factors to be characterized.73 It is synthesized by a number of major cell types involved in angiogenesis and wound repair, and it is found in the ECM bound to heparin. Although the exact mechanism involved in its cellular release remains unknown, it is postulated to occur upon damage to the synthesizing cell. Dermal wounding could thus trigger the release of bFGF protein preexisting in cells in the wound area, allowing active FGF to exert its mitogenic and chemotactic effects on virtually all cells.

Fibroblast growth factor has mitogenic to mesenchymal cells, whereby they influence many of the processes taking place during the proliferative phase of repair. Notably, bFGF promotes endothelial cell migration during granulation tissue formation by induction of cell surface integrins that mediate the binding of endothelial cells to ECM,72 and it is thus considered a potent angiogenic factor, particularly in response to the hypoxic wound environment. Additionally, bFGF can augment epithelialization and may stimulate wound contraction via the enhancement of TGF-β activity. Finally, bFGF exerts effects on matrix synthesis and remodeling by reversing the induction of collagen type I production while simultaneously encouraging collagenase production by fibroblasts.74

Insulin-like Growth Factor

The insulin-like growth factors (IGFs) are structurally similar to proinsulin and, as their name implies, have insulin-like activity. There are two forms, having separate receptors: IGF-1 and IGF-2. Production of IGF-1 by the liver and other tissues is in part regulated by insulin, estrogen, and growth hormone (GH). Indeed, cell proliferation, tissue differentiation, and protein synthesis engendered by GH are mediated, indirectly, through the production of IGFs.

Unlike other growth factors whose primary source during wound repair is the inflammatory cell, substantial levels of inactive IGF, reversibly bound by high-affinity IGF-binding proteins, are present in blood. Once cleaved, the free IGF can exert its autocrine, paracrine, and endocrine actions. Until recently, IGFs were primarily considered mediators of the growth-promoting effects of GH. Lately, it has been shown that IGF-1, released by platelets during clotting and activated by enzymatic activity, low pH, and decreased oxygen tension present in the wound environment, is a potent chemoattractant and mitogen for vascular endothelial cells,75 it enhances epithelial cell proliferation in vitro,76 and it stimulates collagen synthesis by fibroblasts.77 In addition, IGF-1 stimulates epithelial cell membrane protrusion and facilitates cell spreading, which influences the speed of wound epithelialization.69 Interestingly, IGF-1 induces TGF-β1 mRNA and protein expression,78 which implies that it may, indirectly, influence even more aspects of repair.
As mentioned earlier, the impact of intramuscular injections of equine recombinant GH on maturation of limb wounds in horses was initial further wound retraction followed by contraction at a faster rate only after treatment ended.\textsuperscript{87}

Equine IGF-1 cDNA has been cloned and sequenced.\textsuperscript{79}

**Keratinocyte Growth Factor**

Keratinocyte growth factor (KGF)-1 is a member of the rapidly growing FGF family; it is sometimes referred to as FGF-7, and it resembles bFGF (FGF-2). Whereas most FGFs influence proliferation or differentiation of numerous cell types, KGF weakly expressed in skin but strongly upregulated in dermal fibroblasts after wounding,\textsuperscript{80} acts specifically on epithelial cells, in a paracrine fashion.\textsuperscript{81} It stimulates migration and proliferation of these cells, but it also affects differentiation of early progenitor cells within dermal appendages in the wound bed and adjacent dermis. Both KGF-1 and -2 have recently been found to enhance granulation tissue formation during wound repair, by increasing angiogenesis and collagen deposition. Indeed, a recent multicenter clinical trial found that recombinant human KGF-2 (repifermin) accelerated repair of chronic venous ulcers.\textsuperscript{82}

A partial coding sequence for horse KGF-1 (FGF-7) gene is known.\textsuperscript{83}

**Platelet-Derived Growth Factor**

PDGF is a family of isoforms consisting of homo- or heterodimers of products of two genes, the PDGF A-chain gene and the PDGF B-chain gene. Three isoforms of PDGF exist, depending on the bonds formed between the A- and B-chains: AA, AB, and BB.\textsuperscript{84} Although the predominant isoform in human platelets is PDGF-AB, this is species variable and currently unknown in the horse.

The platelet, the first cell to invade the site of trauma, is the largest source of PDGF, although a number of connective tissue cell types are also triggered by wounding to express PDGF-like molecules and receptors. Thus, throughout the normal repair process, wound tissues are continuously bathed in PDGF. PDGF acts initially as a chemoattractant for inflammatory cells and fibroblasts, which it activates in an autocrine fashion. Subsequently it becomes mitogenic for mesenchymal cells through the release of other growth factors—namely, TGF-\(\beta\), from activated macrophages.\textsuperscript{85} In this manner, PDGF may participate in angiogenesis and accelerate epithelialization in normal and pathologic wounds, including those of the horse cornea.\textsuperscript{86} Furthermore, it stimulates the production of ECM components and increases collagenase activity by the wound fibroblast, in this manner enhancing remodeling. Finally, the role of PDGF in contraction remains unclear, although it does not appear to be direct.\textsuperscript{87} To date, PDGF in its recombinant form is the only growth factor commercially available for use as a wound healing stimulant, in particular for the treatment of diabetic foot ulcers.\textsuperscript{88}

**Transforming Growth Factor-\(\beta\)**

Transforming growth factor-\(\beta\) is widely acknowledged as the growth factor with the broadest range of activities in repair, on the basis of both the variety of cell types that produce or respond to it and the spectrum of its cellular responses.\textsuperscript{89} It is an extensively investigated mediator: as of 2004, there were over 20,000 publications on TGF-\(\beta\), and over 2000 articles have been published annually for the past 5 years.\textsuperscript{90} In mammals, three isoforms of TGF-\(\beta\) are currently identified (TGF-\(\beta_1\), \(\beta_2\), and \(\beta_3\)), whose spatial and temporal distributions are specific. TGF-\(\beta_1\) is the most abundant in the majority of tissues, and in platelets it is the only isoform.\textsuperscript{89}

The cDNA for equine TGF-\(\beta_1\) has been cloned and sequenced; it exhibits 99% identity to mature human TGF-\(\beta_1\).\textsuperscript{91}

TGF-\(\beta\) can be synthesized and released from virtually all cell types participating in the repair process. A unique feature of this peptide is that it can regulate its own production by monocytes and activated macrophages in an autocrine manner.\textsuperscript{92} This autocrine induction in a sustained expression at the wound site and extends the effectiveness of both the initial burst of endogenous TGF-\(\beta\) released upon injury and exogenous TGF-\(\beta\) that may be applied to a wound. Thus, this particular growth factor is ubiquitous during repair, when its major effects are to enhance chemoattraction of inflammatory and mesenchymal cells—in particular, fibroblasts—and to modulate the accumulation of ECM. In the former capacity, the effects of TGF-\(\beta\) are exacerbated by its influence on activated macrophages to secrete more TGF-\(\beta\) as well as other angiogenic and fibrogenic mediators. The effects of TGF-\(\beta\) on ECM are more complex and profound than those of any other cytokine, and they are central to increasing the maturation and strength of wounds. In addition to enhancing fibroblast migration to the site of repair, TGF-\(\beta\) regulates the transcription of a wide variety of ECM proteins.\textsuperscript{93} Furthermore, it concurrently inhibits ECM turnover by inducing TIMPs and reducing MMP expression. These particular activities have earned TGF-\(\beta\) the nickname “fibrogenic” cytokine. Indeed, a cause-and-effect relationship has been established between TGF-\(\beta_1\) and fibrosis, in various tissues.\textsuperscript{94} TGF-\(\beta\) has also been found to promote angiogenesis by stimulating endothelial cell migration, differentiation, and tubule formation, as well as by upregulating their integrin receptors. The impact of TGF-\(\beta\) on epithelialization has not been completely elucidated, but it appears to favor epithelial cell migration. Finally, TGF-\(\beta\) enhances wound contraction by inducing \(\alpha\)-SMA expression in granulation tissue myofibroblasts.\textsuperscript{95}

Because of the importance of cytokines in the repair process, we and others have recently examined their contribution to wound repair in the horse, particularly in relation to the development of proud flesh. It is now apparent that local concentrations of fibrogenic TGF-\(\beta_1\) remain elevated throughout the proliferative phase of healing in limb wounds whereas they quickly return to baseline values in body wounds after resolution of acute inflammation.\textsuperscript{46,94,95} Not surprisingly, we found that wounds macrophages and fibroblasts seem responsible for this augmented synthesis.\textsuperscript{96} Correspondingly, TGF-\(\beta\) receptors are abundant in limb wounds, particularly those developing proud flesh, which suggests that the signaling machinery for ECM synthesis is in place to contribute to fibrosis.\textsuperscript{97} Finally, preliminary studies suggest that natural surgical and traumatic\textsuperscript{98}—as well as experimental\textsuperscript{99}—wounds healing with exuberant granulation tissue overexpress fibrogenic TGF-\(\beta_1\) and underexpress antifibrogenic TGF-\(\beta_3\).
Vascular Endothelial Growth Factor

Vascular endothelial growth factor, also known as vascular permeability factor, is a heparin-binding glycoprotein with potent and selective mitogenic, angiogenic, and permeability-enhancing effects on endothelial cells. VEGF is expressed in a range of cells, predominantly macrophages, in response to soluble mediators, cell-bound stimuli, and environmental factors, and it binds to two endothelial cell-specific receptors. Expression is upregulated during early wound repair, in response to tissue hypoxia, and correlates with the density of granulation tissue developing within the wound. Although VEGF activity is considered essential to optimal wound angiogenesis via stimulation of ECM degradation, and via proliferation of, migration of, and tube formation by endothelial cells, it is not critical to wound closure. Cloning of equine VEGF cDNA has been achieved.

Cytokine Therapy

As mentioned several times, horses commonly manifest difficulty with the repair of wounds of the distal extremities; chronic wounds of either the exuberant or indolent type are particularly frustrating. Evidence supporting the role of an abnormal cytokine profile in the pathogenesis of these conditions is mounting, and this has led investigators to manipulate the balance of these mediators in hopes of ameliorating the quality of repair. Although topical application of TGF-β has proven valuable in rodent models for delayed and weak repair. The temperature of the limb of the horse is noticeably less than that of the trunk, and this recovery from severe injury, in particular burn wounds, nutrition is critical only at extremes. Indeed, serum protein must be less than 2 g/dL before wound repair is impeded in the form of slow gain in tensile strength.

Blood Supply/Anemia/Local Oxygen Gradient

There is a strong correlation between the extent of wound repair and regional blood supply. A healing wound depends on local microcirculation to furnish necessary oxygen and other nutrients; therefore, anything that interferes with it inhibits wound repair. Although the normal microcirculation of equine skin is poorly described, it is common knowledge that wound repair is impaired in the distal limb where there is little tissue cover and a relatively poor vascular bed. Interestingly, it has been determined by laser Doppler velocimetry that cutaneous blood flow and volume in the dorsal metacarpal area exceed those of skin at the thoracolumbar junction. This apparent contradiction supports the notion that dermal repair is contingent on more than strictly cutaneous vasculature.

Hypovolemia is the major deterrent to wound repair in anemia, hemorrhage, and shock. Anemia itself does not delay wound repair if blood volume is normal, because low hemoglobin levels are compatible with normal healing. It is tissue oxygen tension, rather than content, that is critical. Oxygen is necessary for tissue metabolism, and, after trauma, for collagen synthesis. An oxygen gradient exists between the nearest functioning capillary and the wound edge. The oxygen tension near a wound capillary is between 60 and 90 mm Hg; however, near the advancing edge of granulation tissue, the oxygen tension approaches 0 mm Hg. This decrease is caused by the diffusion gradient and the consumption of oxygen by cells at the wound margin. Thus, the activities of the new fibroblasts (migration, proliferation, protein synthesis) depend on the rate at which new capillaries are formed, and thus wound tensile strength is limited by perfusion and tissue oxygen tension. Indeed, perfusion during the first postoperative days seems crucial to the outcome of repair, and it is probable that the difference in the accumulation of collagen on day 7 is already established during the early postoperative period.

Although the normal wound environment is characterized by low levels of oxygen tension, hypoxia can be detrimental. On the one hand, cellular synthetic activity is increased by hypoxia, with preferential production of direct angiogenic substances such as VEGF and bFGF as well as indirect mediators such as PDGF and TGF-β. These favor further production of collagen and possibly excessive fibrosis as seen in the horse. On the other hand, hypoxia may be responsible for delayed wound repair by inducing an increase in MMP-1 synthesis, with subsequent excessive degradation of newly formed collagen. Although controversy surrounds the impact of hypoxia, it is certain that ischemic tissues heal poorly and are easily infected. It is thus advisable to select regional anesthesia over local injection of anesthetic agents, particularly those containing epinephrine, to avoid local vasoconstriction when exploring limb wounds during the initial management. Reflex vasoconstriction subsequent to low environmental temperatures is also blamed for delayed and weak repair. The temperature of the limb of the horse is noticeably less than that of the trunk, and this

ELEMENTS INFLUENCING WOUND REPAIR

Endogenous

General Health Status

Wound healing is part of normal body maintenance and depends on the patient’s general state of health. A debilitated horse heals more slowly than a healthy one, but the equine species is less commonly affected by diseases exerting a negative impact on repair (e.g., diabetes, hyperadrenocorticism, liver disease or uremia) than companion animals. Although protein intake is important in the
may have a role in the failure of limb wounds to heal as well as those on the trunk.44

Location
Horses frequently experience pronounced difficulty in repairing wounds on the lower extremities, whereas even extensive wounds of the trunk and head heal remarkably well. Specifically, delays in epithelialization and contraction, as well as the exuberant development of granulation tissue, commonly afflict full-thickness wounds of the distal limbs.43,44 Mechanisms that cause problematic wound repair in the horse limb have yet to be elucidated, although several have been proposed. Better blood supply, a greater amount of adnexal structures, and the thinner epidermis covering the head and neck contribute to the more rapid and cosmetic repair occurring in these areas.10 Furthermore, wounds to the extremities may be near bony prominences and highly mobile joints, and they have an absence of underlying musculature and more contamination compared with body wounds.34,45

Interestingly, a craniocaudal variation in granulation tissue formation has been reported in the rat and is attributed to differing mitotic activity of fibroblasts related to differences in availability of nutrients, hormones, growth factors, or mitotic inhibitors, or to variation in local temperature.22 Although an inherent difference between growth characteristics of trunk and limb fibroblasts was similarly believed to contribute to the development of exuberant granulation tissue in the horse, a study showed that fibroblasts isolated from the horse limb grow significantly more slowly than those of the trunk.21

Prompt repair relies profoundly on the acute inflammatory response to trauma, as any chronicity in this response retards repair and encourages the development of wounds of either an exuberant or an indolent nature, such as those afflicting extremities. The horse displays a deficient yet protracted inflammatory response compared with the pony, especially when wounds are located at the distal aspect of the limb.33,44 Furthermore, leukocytes from ponies are better equipped to kill bacteria than are those of horses.11 Several studies suggest that an imbalance between collagen synthesis and lysis causes the excessive fibrosis exhibited by limb wounds, and they show that the local cytokine profile is skewed in favor of fibrogenic mediators.46,54,55,56 Deficient contraction has also been blamed for poor repair of limb wounds in horses, particularly in comparison with body wounds.43 Although the innate contraction capacities of myofibroblasts from body and from limbs are similar, these cells are poorly arranged in chronic wounds of the limb, which may preclude efficient contractile activity.43 Furthermore, environmental factors emanating from the inflammatory response to injury, such as cytokine profiles, may negatively affect contractility.44

Exogenous

Vitamins (A, E, and C) and Minerals (Zinc)
Vitamin A promotes a healthy integument and enhances immune function through beneficial actions on epithelium. With regard to wound repair, vitamin A exerts positive effects on epithelialization by facilitating cell migration and indirectly controlling cellular growth and differentiation. It also regulates expression of α-SMA in wound myofibroblasts, which may aid wound contraction.81 Vitamin A deficiency is known to negatively influence neutrophil and macrophage maturation and function, which diminishes their migration from local capillaries into the wound bed, as well as phagocytosis and oxidative metabolism. These adverse effects may impair the inflammatory phase of repair. Furthermore, vitamin A deficiency is associated with production of immature fibroblasts, leading to faulty collagen synthesis and deposition.102 Both oral and topical vitamin A supplements mitigate compromised wound repair in animal models, but there is no evidence that administration of vitamin A alters the rate of normal repair.83

The physiologic effects of vitamin E are hypothesized to include antioxidant activity, promotion of optimal immune system function, protection of skin from radiation and excessive sunlight, and acceleration of repair of specific types of wounds. The beneficial effects of vitamin E on wounds (including direct effects on tissue repair and regeneration and indirect effects on immune function) may go beyond the effects of a simple antioxidant.

Physiologic functions associated with vitamin C arise from its ability to act as a reducing agent that balances the potentially harmful byproducts released in oxidative reactions in the body. Vitamin C influences tissue repair and regeneration, in particular with respect to the synthesis of connective tissue. Along with iron it acts as a cofactor for enzymes involved during hydroxylation of proline and lysine in the production of collagen and also during cross-linking of mature collagen. Both of these are critical to the proliferative and remodeling phases of repair. Vitamin C also promotes fibroblast formation, upregulates collagen gene expression, and enhances the biosynthesis of other substances important to wound repair and regeneration, including fibronectin and proteoglycans. Finally, the level of vitamin C in leukocytes is important for phagocytic functions relevant to control of bacteria in wounds.

Zinc is involved in the synthesis or activation of numerous enzymes—in particular, metalloenzymes. It is critical to DNA and RNA synthesis and consequently plays a significant role in wound repair, particularly in the later phases when fibroblast proliferation and collagen synthesis are required.81 During the initial inflammatory phase of repair, zinc concentrations transiently fall; in contrast, the amount of bioavailable zinc in the blood and wound bed rises during the later phases of repair, when concentrations are 15% to 20% higher than those found in intact skin. Although the precise task of zinc in tissue repair and regeneration is not yet known, it is hypothesized to play a significant role in the synthesis of granulation and scar tissue, as well as in epithelialization. Zinc also exerts an anti-inflammatory effect on phagocytic cells, important to late repair and closure. On the other hand, high concentrations of zinc may be detrimental to repair for the same reason. Zinc deficiency adversely affects inflammatory cells. Studies in both animal models and humans demonstrate that zinc deficiency is associated with an increased risk for chronic wounds.61
Nonsteroidal Anti-inflammatory Drugs
Selective inhibition of either cyclooxygenase (COX)-1 (constitutive) or COX-2 (induced by lipopolysaccharide, nitric oxide, and various cytokines) is the basis for the mechanism of action of nonsteroidal anti-inflammatory drugs (NSAIDs). The activity of these rate-limiting enzymes on membrane-derived arachidonic acid generates various eicosanoids, which mediate inflammation and induce fibroblast proliferation and collagen production. COX-2 is the predominant isozyme in all stages of the inflammatory response, and its upregulation is accountable for persistent inflammation because the reaction products are responsible for many of the cytotoxic effects of inflammation.16

Inflammation protects against infection and is a precursor to the subsequent proliferative phase of repair through the action of macrophage-generated mediators that initiate migration and proliferation of the mesenchymal cells involved in angiogenesis, fibroplasia, and epithelialization. Consequently, controversy surrounds the use of NSAIDs in the early period after trauma, when the normal inflammatory response should not be inhibited. For example, high doses of NSAIDs administered immediately after creation of linear ala incisions in ponies delayed repair,17 and suppression of inflammation by COX-2 inhibition reduced the extent of granulation/scar tissue without compromising tensile properties of mouse wounds.18 Although NSAIDs appear to have little effect on the ultimate course or quality of repair when dispensed in pharmacologic doses, selective anti-inflammatory agents, such as COX-2 inhibitors, can be fine-tuned to suppress the imbalances of inflammation, thus leading to a more ideal healing response.

In contrast, chronic inflammation is characterized by excess and persistent neutrophil and macrophage activity and may forestall the normal repair sequence, leading to a number of diseases typified by disproportionate scarring. In these cases, NSAIDs, especially COX-2 selective inhibitors, may be effective in the prevention of excessive scarring.

Corticosteroids
Regardless of the tissue implicated, topical and systemic administration of corticosteroids appears to retard wound repair, depending on the specific glucocorticoid involved and the timing, concentration, and duration of therapy.19 Cortisone stabilizes lysosomal membranes and consequently inhibits the normal inflammatory response to trauma. This leads to a delay in repair, although ultimate wound strength does not seem affected. Other mechanisms whereby glucocorticoids may alter various phases of repair include angiostasis,20 decreased rate of fibroblast proliferation with consequent inhibition of protein synthesis, possibly through downregulation of fibrogenic TGF-β21 and inhibition of KGF production in fibroblasts, which may impair epithelialization.122

Traumatic wounds in the distal extremities of horses appear predisposed to an excessive fibroblastic response, leading to the development of proud flesh. Because corticosteroids limit proliferation of both fibroblasts and endothelial cells, topical application may be beneficial in this particular situation. Indeed, glucocorticoids are used extensively by equine practitioners in the treatment of wounds, with mostly favorable results.123 However, one application at the first sign of excessive fibroplasia is all that is needed—continued application may exert negative effects on wound contraction and epithelialization.

Bandages
Second-intention wound repair depends on contraction and epithelialization. Any therapy that accelerates either of these mechanisms would be a desirable adjunct to the management of wounds in the horse, particularly those located at the distal aspect of the limb and complicated by excessive fibroplasia and subsequent poor strength and cosmetic appearance. Although moist wound healing, such as that occurring under semiocclusive and fully occlusive synthetic dressings, favors rapid epithelialization and cosmetic repair in other species, it has been shown to encourage excessive growth of granulation tissue and delay subsequent repair when applied to wounds located on the distal limb in the horse.99,124,125 An exception is the nonadherent and fully occlusive silicone dressing that we have recently shown to prevent the formation of exuberant granulation tissue and improve tissue quality in repairing limb wounds of horses.25 Various semiocclusive biologic dressings are available for use in the horse, such as amnion, allogeneic skin, peritoneal grafts, and porcine small intestinal or urinary bladder submucosa.124 To date, the only one of these showing beneficial effects when used on granulating limb wounds or graft sites is species-specific amnion dressing.126,127 For more details on bandaging and wound management see Chapter 26.

CHAPTER 6

Metabolism and Nutritional Support of the Surgical Patient

Elizabeth A. Carr

In the last two decades, a tremendous advancement in the care and treatment of the critically ill equine patient has taken place. Survival rates from colic surgery have increased, and large-animal intensive care units are found in most, if not all, major university hospitals and referral practices across the United States and most of Europe. Critical to this success is presurgical evaluation and patient triage. The physical examination data as well as laboratory and diagnostic information are carefully collected and analyzed to determine the severity of the disease process. Any underlying abnormalities and any metabolic derangements that may affect the outcome negatively are carefully determined. Patients may receive fluids, anti-inflammatories, colloids, oxygen insufflation, and other medications prior to anesthesia to ensure that a hemodynamically and metabolically stable patient is taken to the induction stall. The surgical technique is designed to minimize trauma, resolve the underlying problem, and keep postoperative complications at a minimum. After recovery, the patient may be continued on intravenous fluids to maintain hydration, as well as other therapeutics to minimize or prevent postoperative complications, including ileus, pain, and infection, and to maximize the chance of recovery. Despite this proactive approach to treatment and support of adult equine patients, rarely is their nutritional status considered in the initial therapeutic plan. Preoperative and postoperative nutritional status and

Metabolism and Nutritional Support of the Surgical Patient
Elizabeth A. Carr

In the last two decades, a tremendous advancement in the care and treatment of the critically ill equine patient has taken place. Survival rates from colic surgery have increased, and large-animal intensive care units are found in most, if not all, major university hospitals and referral practices across the United States and most of Europe. Critical to this success is presurgical evaluation and patient triage. The physical examination data as well as laboratory and diagnostic information are carefully collected and analyzed to determine the severity of the disease process. Any underlying abnormalities and any metabolic derangements that may affect the outcome negatively are carefully determined. Patients may receive fluids, anti-inflammatory, colloid, oxygen insufflation, and other medications prior to anesthesia to ensure that a hemodynamically and metabolically stable patient is taken to the induction stall. The surgical technique is designed to minimize trauma, resolve the underlying problem, and keep postoperative complications at a minimum. After recovery, the patient may be continued on intravenous fluids to maintain hydration, as well as other therapeutics to minimize or prevent postoperative complications, including ileus, pain, and infection, and to maximize the chance of recovery. Despite this proactive approach to treatment and support of adult equine patients, rarely is their nutritional status considered in the initial therapeutic plan. Preoperative and postoperative nutritional status and
nutritional support are clearly linked to morbidity and mortality in humans. Malnutrition has been shown to negatively impact survival, immune function, wound healing, and gastrointestinal function, and it probably negatively affects numerous other processes.

This chapter will discuss the metabolic consequences of food deprivation, the pathologic metabolic responses to illness, nutritional requirements in health and disease, and the indications for and types of nutritional supplementation.

**INDICATIONS FOR NUTRITIONAL SUPPORT**

The need for interventional nutritional support depends on a number of factors. The healthy adult horse that is undergoing elective surgery and has a body condition score of 4 or 5 (out of 9) rarely requires nutritional supplementation (Box 6-1). These individuals can easily tolerate food deprivation for 48 hours. The majority of healthy adult horses undergoing elective surgery have food withheld for a period of 6 to 12 hours preoperatively, and it is reintroduced after recovery when the animal is deemed capable of eating and swallowing effectively. During this period of starvation, energy demands are met by glycogen reserves, with little effect on overall metabolism.

Regardless of the type and complexity of the surgical procedure, nutritional support should be considered in patients with an increased metabolic rate (e.g., young growing animals), individuals presenting with a prior history of malnutrition or hypophagia, patients with underlying metabolic abnormalities that could worsen with food deprivation, and individuals with disorders such as severe trauma, sepsis, or strangulating bowel obstruction that result in an increased energy demand. Underweight horses require nutritional support earlier. Obese or overconditioned individuals, particularly pony breeds, miniature horses, and donkeys, as well as lactating mares are at risk for developing hyperlipemia and should receive nutritional support if their serum triglycerides are higher than normal values. Older horses, or individuals diagnosed with equine Cushing's syndrome and the more recently described peripheral Cushing's syndrome, are insulin resistant and at greater risk for developing hyperlipemia and fatty infiltration of the liver. If food deprivation is prolonged or there is a concern regarding the individual's desire or ability to eat, early intervention is indicated to prevent more severe malnutrition.

**PURE PROTEIN/CALORIE MALNUTRITION**

The average, healthy adult horse can easily tolerate food deprivation (pure protein/calorie malnutrition [PPCM] or simple starvation) for 24 to 72 hours with little systemic effect. A decline in blood glucose concentration occurs with food deprivation, insulin levels fall, and energy demands are initially met via glycogenolysis, resulting in an increase in the breakdown of liver glycogen stores. As starvation progresses, glycogen is mobilized from other tissues, including muscle. Lipid mobilization is triggered by alterations in insulin or glucagon levels and the activity of hormonesensitive lipase. As glucose becomes limited, many body tissues begin to rely on fatty acid oxidation and the production of ketone bodies as energy sources. Glycerol produced from lipid degradation, lactate from the Krebs cycle, and amino acids from muscle tissue breakdown continue to be utilized for gluconeogenesis to provide energy to glucose-dependent tissues (central nervous system and red blood cells). This response to starvation correlates with an increase in circulating levels of growth hormone, glucagon, epinephrine, leptin, and cortisol and a decrease in insulin and thyroid hormones. These hormone fluxes are an afferent stimulus for the hypotalamic response to starvation resulting in an increased drive to eat and a decrease in energy expenditure. Metabolism slows in an effort to conserve body fuels, and the body survives primarily on fat stores, sparing lean tissue.

Individuals with preexisting PPCM are at a disadvantage when intake is restricted because of surgery or illness. In the malnourished or cachectic human patient, presurgical

Scoring is based on visual appraisal and handling (particularly in scoring horses with long hair).
nutritional supplementation has been shown to positively influence both survival and morbidity. Early nutritional supplementation should be strongly considered in animals presenting with preexisting PPCM.

**METABOLIC RESPONSE TO INJURY**

The metabolic response to injury (e.g., surgical manipulation, critical illness, sepsis, trauma), unlike the response to PPCM, is characterized by an increased metabolism and the onset of a catabolic process leading to excessive breakdown of tissue proteins. This metabolic state is the result of a complex interaction of inflammatory cytokines (interleukin [IL]-1, IL-2, IL-6, tumor necrosis factor [TNF]-α, and γ-interferon; see Chapter 2) released at the site of injury or inflammation, circulating hormones released in response to stress and injury (hypothalamic-pituitary-adrenal axis), and neurotransmitters (sympathoadrenal axis).7 Infusion of cytokines including IL-6 and TNF-α results in stimulation of corticotrophin, cortisol, epinephrine, and glucagon, leading to an increase in the resting metabolic rate and lipolysis.8,9 TNF-α activation of nuclear factor kappa (NFκα)-β results in stimulation of proteolytic pathways.10 In response to injury, there is an increased metabolic activity of the brain. Afferent nerve activity and brain stimulation may result in autonomic nerve stimulation with direct effects on hormone secretion; for example, splanchnic nerve stimulation as a result of injury results in increased glucagon secretion and hyperglycemia.11 Afferent nerve activity from the injured site also results in hypothalamic-pituitary activation, increasing activity of cortisol, catecholamines, growth hormone, aldosterone, and antidiuretic hormone.12 In fact, in humans, prolonged infusions of glucagon, cortisol, and epinephrine result in increased protein breakdown and elevated resting metabolic rate.13 Prolonged elevation of cortisol is associated with onset of insulin resistance. In addition, peripheral nerve endings have been shown to exist on adipocytes, and the stimulation of adipocytes results in increased lipolysis.

During illness or after trauma, food intake frequently falls. However, despite this decline, the adaptive responses to starvation do not occur. Hepatic gluconeogenesis continues and rapid protein catabolism develops. There is an increased mobilization of stored fuels and metabolic cycling, resulting in heat production and energy loss. Insulin stimulation develops and hyperglycemia may occur despite the absence of food intake. In severe metabolic stress, the body appears to preferentially utilize skeletal muscle as a metabolic fuel (as opposed to the situation in PPCM, when fat metabolism is the principal source of energy). The adaptive switch to fat utilization is limited, in part because of increased levels of circulating insulin. The result is an increase in lean tissue breakdown, visceral organ dysfunction, impaired wound healing, and immunosuppression.7–13 Nitrogen losses during this catabolic response may be as high as 20 to 30 g/day versus 4 to 5 g/day in a human experiencing PPCM. Excess protein breakdown and muscle disuse because of inactivity result in muscle weakness and increased morbidity. Because sodium and water retention are a component of this response, weight loss frequently goes unnoticed. Cytokine production results in behavioral changes, including anorexia and decreased activity. Food deprivation during this hypermetabolic/catabolic state results in a much greater loss of lean muscle mass and visceral protein than would be expected during simple starvation. A healthy human allowed access to water can survive approximately 3 months with food deprivation or PPCM. In contrast, the same individual with a critical illness would survive approximately 1 month, and those with preexisting malnutrition, less than 2 weeks.

Although nutritional supplementation will reverse the catabolic processes occurring during simple starvation, it will not completely reverse those occurring during metabolic stress, because as long as tissue injury persists, catabolic processes are maintained. In the critically ill patient, protein catabolism continues despite protein supplementation in the diet. However, nutritional supplementation does have benefits in minimizing the severity of protein loss, providing both essential and conditionally essential amino acids, vitamins, and minerals, and in decreasing morbidity associated with illness.

Although the metabolic response to surgical injury is not likely to be as severe as that expected with sepsis, severe trauma, or other critical illnesses, an increase in metabolic rate is seen postoperatively in humans undergoing simple elective surgery. The combination of an increased energy demand and the metabolic processes already discussed can result in significant loss of lean body mass. These changes may not affect survival, but they can significantly impact the return to performance of a competitive athlete. In equine patients with severe surgical trauma, prolonged recoveries, or complications such as infection and laminitis, food deprivation almost certainly affects overall recovery.

**METABOLIC REQUIREMENTS**

The total energy of a feedstuff is divided into the digestible energy (DE) and the nondigestible energy. Digestible energy is further divided into metabolic energy (which is used to provide energy) and that which is lost or nonmetabolizable, such as gases produced and urea excreted in the urine. By convention, energy requirements are calculated in terms of digestible energy.

**Adults**

The amount of DE needed to meet the maintenance energy requirements (DE<sub>m</sub>) of the normally active, non-working horse can be estimated using the following formulas:

- For horses weighing less than 600 kg,
  \[
  \text{DE}_{m} \text{ (Mcal/day)} = 1.4 + (BW \times 0.03) 
  \]

- For horses weighing greater than 600 kg,
  \[
  \text{DE}_{m} \text{ (Mcal/day)} = 1.82 + (BW \times 0.0383) - (BW \times 0.000015).
  \]

where BW is body weight in kilograms, and 1 Mcal equals 1000 kcal. Alternatively, these requirements can be estimated to be approximately 33 kcal/kg per day.

- For horses weighing less than 600 kg,
  \[
  \text{DE}_{m} \text{ (Mcal/day)} = 1.4 + (BW \times 0.03) 
  \]

- For horses weighing greater than 600 kg,
  \[
  \text{DE}_{m} \text{ (Mcal/day)} = 1.82 + (BW \times 0.0383) - (BW \times 0.000015).
  \]
The resting energy requirement (DEr) is the amount of energy required for maintenance (neither weight gain nor weight loss) of the completely inactive animal and is determined using a metabolism stall in a thermoneutral environment. The result is approximately 70% of the maintenance energy, and it can be calculated using the following formula:

\[ \text{DEr (Mcal/day)} = (\text{BW} \times 0.021) + 0.975. \]

The maintenance energy requirements of a horse can be affected by several factors, including its age, size, and physical condition; the amount and type of activity; and environmental factors. Even when all these factors are controlled, individual variation occurs.

**Increased Energy Demand**

Energy requirements in the pregnant mare do not significantly increase until late gestation and are estimated to be 1.1, 1.13, and 1.2 times the DEr, respectively, in the last 3 months of gestation. During lactation, energy demands peak over the first 3 months and then decline toward weaning and can be calculated using the following equations:

- **In the first 3 months of lactation,**
  - for 300- to 900-kg mares,
    \[ \text{DE (Mcal/day)} = \text{DEr} + (0.03 \times \text{BW} \times 0.792), \]
  - for 200- to 299-kg mares,
    \[ \text{DE (Mcal/day)} = \text{DEr} + (0.04 \times \text{BW} \times 0.792). \]
- **After 3 months of lactation,**
  - for 300- to 900-kg mares,
    \[ \text{DE (Mcal/kg)} = \text{DEr} + (0.02 \times \text{BW} \times 0.792), \]
  - for 200- to 299-kg mares,
    \[ \text{DE (Mcal/day)} = \text{DEr} + (0.03 \times \text{BW} \times 0.792). \]

The energy and protein requirements for the hospitalized surgical patient are not known and probably vary depending on disease state, environment, and level of fitness of the individual. However, they are likely to be close to the resting or maintenance energy requirements. In humans, multipliers have been used to estimate the energy requirements in certain conditions, including severe sepsis, trauma, and burn injuries. However, the increased metabolic demands of illness or surgical trauma and recovery are likely to be balanced by the inactivity of the patient during hospitalization. Consequently, these multipliers may overestimate the caloric requirement of certain illnesses. The exceptions to this are individuals with extreme trauma, burns, or severe sepsis; surgical conditions that require intestinal resection; and patients with large areas of devitalized tissue (e.g., patients with clostridial myositis undergoing multiple fasciotomies). When estimating the energy requirements of the majority of surgical patients, resting energy requirements are an acceptable target. If the patient tolerates nutritional supplementation at this rate, the amount can be gradually increased to meet maintenance needs.

**Foals and Weanlings**

Foals and young horses that are growing have the highest energy demands. Mare’s milk has been reported to provide between 500 and 600 kcal of energy per liter. A healthy neonatal foal consumes between 4500 kcal (4.5 Mcal) to 7800 kcal per day. This equates to a metabolic rate of between 100 and 173 kcal/kg per day. The resting metabolic rate in the healthy sedated foal has been calculated to be between 45 and 50 kcal/kg per day. As previously discussed, it is unclear whether a sick individual truly has a higher metabolic rate than a healthy individual. A recently bent sick foal is expending significantly less energy than its healthy counterpart in terms of activity level, but disease and its effect on metabolic rate and catabolism must be considered. As with adults, it is probably best to start nutritional supplementation at approximately the DEr, particularly if starting with the enteral route. If tolerated, it is recommended that this be gradually increased toward growth requirements over a shorter period of time than might be used to increase the adult animal’s caloric intake. If using mare’s milk or a milk replacement of similar caloric content, DEr would equate to feeding the equivalent of 10% of the foal’s body weight per day. Clinical experience suggests that this would be sufficient in the initial 12 to 24 hours, but additional nutritional support would be required to ensure adequate intake for healing and growth.

The largest growth rate occurs during the first month of life. The following formula can be used to estimate and adjust the energy requirement, in Mcal DE per day, for growth of weanlings and young growing horses:

\[ \text{DEr} + \{[4.81 + (1.17 \times M) - (0.023 \times M^2)] \times ADG\}, \]

where M is months of age, ADG is average daily weight gain in kilograms, and BW is body weight.

More comprehensive reviews related to the metabolic needs of active and young growing horses are available for readers who need them.

**PROTEIN REQUIREMENTS**

Protein intake must be adequate not only for energy requirements but also to ensure that protein catabolism is minimized. Maintenance requirements for crude protein (CP) in the adult horse can be estimated using the following equation:

\[ \text{CP (in grams)} = 40 \times \text{DEr} \text{ (in Mcal/day)} \]

For example, a 500-kg horse with a DEr of 16.5 Mcal/day would require 660 g of protein per day. Alternatively, protein requirements can be estimated as 0.5 to 1.5 g protein per kilogram of the horse’s body weight per day, or 250 to
750 g/day for a 500-kg horse. The higher end of this estimate should be used when calculating protein needs in a sick patient.

**VITAMIN REQUIREMENTS**

Vitamins are organic compounds that are important in many enzymatic functions and metabolic pathways. Fat-soluble vitamins include vitamins A, K, D, and E. Water-soluble vitamins include the B vitamins and vitamin C. Vitamin K and all the B vitamins with the exception of niacin are synthesized by the microbial population in the horse’s large colon and cecum. Vitamin D, vitamin C, and niacin are produced by the horse, whereas the precursors to vitamin A, beta-carotene, and vitamin E must be ingested. The need for supplemental vitamins and minerals depends on the type and duration of supplementation. Fat-soluble vitamins are stored in body tissues and generally do not require supplementation for short periods of anorexia. Complete pelleted diets have vitamins and minerals added to meet the requirements set by the National Research Council. When feeding a component diet or a parenteral diet, vitamin and mineral supplementation is necessary to ensure adequate intake.

**ASSESSMENT OF NUTRITIONAL SUPPORT**

Body weight should be measured daily to determine if nutritional support is adequate to maintain body weight. The most accurate method is to use a walk-on floor scale. A weight tape is a useful alternative when a scale is not available. Weight tapes are used to measure the girth just behind the elbow; the circumference correlates with pounds or kilograms. Weight tapes are relatively accurate in predicting the weight of small horses (less than 350 kg) and large ponies (350 to 450 kg). Weight tapes have been shown to be less accurate in estimating weight in heavy stock breeds and Thoroughbred horses.18 However, in the hospital setting, their value lies in determining the overall trend of body weight, not the actual number.

Body condition scores are used to subjectively determine the animal’s body fat stores and are useful to evaluate the long-term nutritional status of the animal (see Box 6-1). Body condition scores are less useful than a scale for determining smaller weight gains and losses in a hospital situation, but they are more accurate for predicting fat stores.

Diet and hydration status can alter body weight by as much as 5% to 10%. For example, a 500-kg horse that presents with colic may be 7% dehydrated at admission. At the time of exploratory celiotomy, the large colon may be emptied to facilitate correction of a surgical lesion. Rehydration of this animal would result in a weight increase of 35 kg. The large colon and cecum can hold between 75 and 90 L of ingesta; removal of a portion of the contents could result in a weight loss of 50 kg or more. Consequently, weight changes need to be considered in light of hydration status, feed intake, and any procedures that have occurred.

**ENTERAL NUTRITION**

In the critically ill patient with poor perfusion and decreased oxygen delivery to the tissues, the gastrointestinal tract is frequently the most vulnerable organ. Decreased oxygen delivery has been shown to increase mucosal permeability, resulting in increased translocation of bacteria and absorption of bacterial toxins.9,20 Inflammatory mediators, produced in the gut as a result of ischemia, are absorbed across the damaged mucosa and enter the portal and systemic circulations; this absorption has been implicated in the onset of septic shock or multiorgan failure.21 Enteral nutrition increases total hepatosplanchnic blood flow in healthy patients, resulting in greater oxygen delivery to the mucosa. In a rat model of *Escherichia coli* sepsis, enteral feeding of glucose resulted in improved intestinal perfusion rates.22 Enteral nutrition maintains functional and structural integrity of the gut; the absence of enteral nutrition results in mucosal atrophy, increased gut permeability, and enzymatic dysfunction in critically ill human patients.23

Enteral nutrition is a trophic stimulus for the gastrointestinal tract both directly via the presence of nutrients and indirectly via stimulation of trophic hormones such as enteroglucagon. Early enteral nutrition (EEN) is the initiation of enteral feeding within 48 hours after surgery. In a large clinical study of surgical and trauma patients, EEN significantly decreased morbidity and length of stay when compared with delayed enteral nutrition and parenteral nutrition.24 Enteral nutrition has a protective effect against bacterial translocation across the ischemic intestinal wall. In addition, EEN has been shown to blunt the hypermetabolic/catabolic response to injury in several human and animal models.2 During the hypermetabolic, catabolic state seen with injury or illness, many amino acids, such as glutamine, become conditionally essential. Glutamine is an important fuel for lymphocytes, hepatocytes, and mucosal cells of the gut. During catabolism, glutamine levels may become insufficient to meet these energy demands. The addition of glutamine to both enteral and parenteral diets may improve gastrointestinal function and mucosal cell healing.24

Although the decision to supply supplemental nutrition may be clear, the route of supplementation must be considered in light of the original insult, surgical manipulations, and postoperative status of the patient. The enteral route is always preferred when the gastrointestinal tract can be used. Patients with overwhelming bowel ischemia, intestinal resection, and anastomosis or postoperative ileus may not be the best candidates for EEN. However, concerns about the strength and diameter of anastomotic sites after surgical resection and about the risk of obstruction at the anastomotic site are valid concerns; consequently, when enteral feeding is to be instituted, the type of diet should be carefully considered. Patients with a high risk of postoperative ileus or with a narrow anastomotic site may be better off started on parenteral nutrition and then gradually reintroduced to enteral nutrition. Alternatively, a liquid enteral diet may be instituted until healing is sufficient to allow introduction of roughage.

Types of enteral nutrition can vary from normal feedstuffs (i.e., grains, hay, and complete pelleted diets), slurry diets composed primarily of normal feedstuffs (Table 6-1), and

Liquid diets containing component requirements (Table 6-2). In horses with decreased appetite or complete anorexia, the choices are limited to those diets that can be administered through a nasogastric tube. Complete pelleted diets offer several advantages: they are relatively inexpensive, they are well balanced for the maintenance requirements of the adult horse, and they contain fiber. Fiber is beneficial in increasing colonic blood flow, enzymatic activity, and colonic mucosal cell growth and absorption. The major disadvantage of pelleted diets is the difficulty of giving them via nasogastric intubation. Both human and equine liquid formulations are available and have been used as enteral nutrition support in horses.

Alternatively, diets prepared using specific components have been described. Corn oil may be added to the diet to increase the caloric content. The use of human products for the full-size horse can be very expensive, and these products have been associated with diarrhea. Liquid diets may be given via continuous flow using a small nasogastric tube or via periodic intubation and larger meals. When using pelleted diets, approximately 1 kg of a pelleted complete feed is soaked in approximately 4 L of water. Once dissolved, an additional 2 L of water is added and the slurry is administered via a large-bore nasogastric tube. Slurry diets made from complete pelleted feeds will not pass through a nasogastric tube using gravity alone and must be pumped in using a marine-supply bilge pump. If a bilge pump is not available or a large-bore tube cannot be passed, pulverizing the pellets prior to adding water may improve flow. The horse should be checked for the presence of gastric reflux prior to administration, and the slurry should be pumped slowly with attention paid to the horse’s attitude and reaction.

The stomach volume of an adult, 450-kg horse is approximately 9 to 12 L, and a feeding should not exceed 6 to 8 L. This volume should be adjusted for smaller horses. Long-term placement of nasogastric tubes is not without the risk of complications. Small-bore, softer (polyurethane) tubes are recommended if intubation is prolonged, but these generally preclude the use of slurry diets. Alternatively, intermittent placement of a nasogastric tube is effective in decreasing complications, but this can be difficult and at times traumatic to the patient. When instituting enteral feeding, particularly in a patient with prolonged anorexia, it is best to start gradually, increasing the amount fed over several days. A maximum of 50% of the calculated requirements should be fed in the first 24 hours. If the patient tolerates the supplementation, it can be increased over the next few days until full supplementation is achieved. Rapid changes in intake, particularly with component feeding or high-fat diets, may be associated with colic or diarrhea.

**PARENTERAL NUTRITION**

Parenteral nutrition (PN) is used to supply nutrition when the enteral route is unavailable. Parenteral nutrition can provide partial nutritional support (PPN) or total nutritional support (TPN). In the adult horse, it is most commonly used to supply partial nutrition when oral intake is insufficient or inappropriate. Horses with proximal enteritis, colitis, postoperative ileus, esophageal lacerations, or obstructions can receive nutritional support until resolution of the underlying problem allows reinstitution of enteral feeding. Recumbent or dysphagic animals at risk for aspiration pneumonia, individuals with preexisting protein calorie malnutrition or increased energy demands (late gestation, early lactation, and young, growing animals), and those with decreased feed consumption should also be considered as candidates for partial or total parenteral nutrition.

Depending on the desired goals and duration of supplementation, solutions containing various amounts of carbohydrate, amino acids, lipids, vitamins, electrolytes, and minerals may be formulated. Carbohydrate is commonly provided using 50% dextrose solutions (2525 mOsm/L) that contain 1.7 Kcal/mL. Isotonic lipid emulsions contain principally safflower and soybean oil, egg yolk phospholipids, and glycerin and come in 10% and 20% solutions. Amino acid preparations are available in several concentrations: 8.5% and 10% solutions are most commonly used in veterinary medicine. Solutions containing both essential and conditionally essential amino acids are preferable.

Components that may be added to parenteral nutrition include electrolyte solutions and vitamin and mineral supplements. Multivitamin supplements for humans are available and may be added directly to PN solutions. Some vitamins can be given orally (vitamins C and E) or added to crystallloid solutions (B vitamins). Fat-soluble vitamins are stored in body tissues and rarely need to be supplemented unless prolonged periods (weeks) of anorexia occur. Macrominerals, if required, are best supplemented in separate crystallloid solutions, because divalent cations may destabilize lipid emulsions. Although sick animals require trace minerals, such supplementation is rarely given except to patients receiving parenteral nutrition as their sole nutritional source for prolonged periods (greater than 7 days).

Resting energy requirements should be used when calculating PN volumes for adult animals, but protein requirements should be determined using maintenance requirements (see Box 6-1) or estimated using the following...
formula (as described under “Protein Requirements,” earlier):

0.5 to 1.5 g protein per kilogram BW per day.

The higher end of this formula is recommended in sick, compromised patients. The ratio of nonprotein calories to nitrogen should be at least 100:1 in the final solution. Lipids should provide approximately 30% to 40% of the nonprotein calories whenever possible. The addition of lipids to PN is beneficial in patients with persistent hyperglycemia or hypercapnia, as this reduces the dependency on glucose as the principal energy source. The amount of fat utilization will depend on the amount of carbohydrate provided, with fat storage occurring in the presence of excess carbohydrate calories.

The preparation of PN should be performed under a laminar flow hood using aseptic techniques. Lipids should be added last to prevent destabilization of the emulsion in acidic dextrose solutions. Parenteral solutions are an excellent medium for growth of bacteria and should be used within 24 hours of preparation. Prior to use, they should be kept in a dark, cool area to minimize degradation and loss of vitamins. Because these solutions are hyperosmolar, delivery through a central venous catheter is recommended. Ideally, a separate catheter or portal is designated for parenteral nutrition only. Catheter placement and line maintenance should be performed using strict aseptic technique and all lines changed daily. We generally place a 14-gauge double-lumen catheter (Arrow catheter, Arrow International, Reading, Pa.) and designate one port for parenteral nutrition. Gradual introduction of parenteral nutrition is recommended to decrease risk of complications. Initial infusion rates should provide approximately 25% to 50% of the calculated requirement over the first 24 hours. If tolerated, the rate of infusion can gradually be increased over the next few days to provide 100% of the calculated requirement.

Complications of parenteral nutrition include hyperglycemia, hyperammonemia, hyperlipemia, elevation of serum urea nitrogen, thrombophlebitis, and sepsis. Lipid infusions have been associated with allergic reactions, hyperlipemia, alterations in liver function, and fat embolism. Insulin resistance seen with systemic inflammatory response syndrome can result in hyperglycemia and rebound hypoglycemia when rates are altered too rapidly. Although solutions containing lipids are very useful in providing additional calories, their use should be determined on a case-by-case basis. Lipids should be avoided in patients with a predisposition to or a preexisting hyperlipemia or an underlying liver dysfunction. Thrombocytopenia, coagulopathy, fat embolization, coagulopathies, and alterations in cellular immunity are reported with lipid infusions. Triglyceride levels and platelet counts should be monitored regularly when lipids are added to PN solutions.

Monitoring should include daily assessment of serum electrolytes, blood urea nitrogen, triglycerides, and ammonia and liver function during the acclimation period. Blood glucose should be monitored every 4 to 6 hours and the rate adjusted to maintain blood glucose within the established normal range. If costs are a concern, blood values may be monitored less frequently once a steady state has been achieved.

CHAPTER 7

Surgical Site Infection and the Use of Antimicrobials

R. Wayne Waguespack
Daniel J. Burba
Rustin M. Moore

One of the most serious complications associated with surgery is the development of infection after an operation. Postoperative surgical site infections (SSIs) are a major source of morbidity and even mortality. The risk of SSI in horses varies greatly depending on interactions between factors that can be categorized as attributable to host, microorganisms, and surgery. Numerous discoveries have contributed to the advancement of modern surgery, such as Semmelweis’s recognition of a surgeon’s hands as a source of contagion, Lister’s use of antiseptics to reduce the risk for mortality among newborn babies and their mothers, the discovery of penicillin and the resultant antimicrobial era, and the importance of the timing of antibiotic prophylaxis as demonstrated by Burke. These discoveries have been adapted to modern veterinary surgery. However, despite advances in surgical techniques, infection control, and antibiotic prophylaxis, postsurgical infections remain a problem in the equine patient.

WOUND CLASSIFICATION

The presence of purulent drainage from the incision site has typically been the clinical definition of an SSI. However, infection may be present in or around a site that communicates with the incision, complicating the definition of SSI. Therefore, to create a uniform classification of SSI, the Centers for Disease Control and Prevention (CDC) established definitions for surveillance and epidemiologic purposes. In 1992, the CDC redefined surgical wound infections as SSIs to include the incision, regional extension, and organ or visceral infection, but not more-distant infections (e.g., postoperative pneumonia). Distant infections are considered complications and are not classified as SSIs because they are not directly associated with the surgical incision. For surveillance and classification purposes, SSIs are placed into three categories: superficial incisional SSI (involving skin and subcutaneous tissues), deep incisional SSI (involving the fascial and muscle layers), and organ or space SSI (involving any part of the anatomy other than the incision that is opened or manipulated during the surgical procedure) (Table 7-1).

Veterinary medicine has used the wound classification system developed by the National Academy of Sciences and the National Research Council (Table 7-2). This classification system is based on intrinsic intraoperative microbial contamination. Originally, it was believed that as the degree of microbial contamination increased, so did the overall incidence of SSI; however, this may be misleading in equine surgery. In clinical studies in the horse, the correlation between wound classification and surgical infection has been shown to vary greatly between soft tissue and orthopedic procedures. In equine abdominal surgery, the performance of enterotomy or resection did not influence the incidence of SSI. Preexisting dermatitis, poor intraparative drape adherence, high number of bacterial colony-forming units (CFU) obtained from the celiotomy incision site immediately after recovery from anesthesia, and high number of CFU obtained from the surgery room environment are risk factors associated with abdominal SSI. In contrast, there is a strong association between the risk of postoperative infection and surgical wound classification for equine orthopedic procedures, where surgical wound classification has the strongest association. Clean-contaminated surgeries are approximately 24 times more likely to develop a postoperative SSI than are clean surgeries. For example, long-bone surgeries have a 5.1-fold greater risk of surgical infection than do procedures involving the articular surface.

INFECTION AND SOURCES OF MICROORGANISMS

A variety of microorganisms are capable of causing SSIs in horses, but the most common agents are bacteria. In horses, coagulase-positive and coagulase-negative staphylococci, followed by members of the family Enterobacteriaceae, species of Streptococcus and Pseudomonas, and anaerobes, were the most common pathogens isolated from infections after joint surgery. Postoperative infections after fracture repair were most often caused by Enterobacteriaceae, followed closely by streptococci (Table 7-3). In horses with peritonitis after abdominal surgery, streptococci, Enterobacteriaceae, Actinobacillus species, and anaerobes, including species of Fusobacterium, Peptostreptococcus, Clostridium, and Prevotella, and Bacteroides fragilis were found. Infection often results from microorganisms introduced into the surgical site at the time of surgery. It is believed that within 24 hours of a surgical procedure, a surgical site is sufficiently sealed to be resistant to microorganism entry.

Sources of microorganisms that infect surgical sites include endogenous sources (the patient’s flora), remote infections in the surgical patient, and exogenous sources such as operating room personnel, the environment, and the air. Most SSIs are believed to originate from direct inoculation of the patient’s endogenous flora at or near the surgical site during surgery. For example, contamination during ventral median celiotomies in horses was caused by streptococci, staphylococci, and Escherichia coli, which are representative of the horse’s endogenous flora. Endogenous microorganisms located at a distance from the surgical site may also be a source of infection. It was shown that human albumin microspheres applied as tracer particles on a patient’s skin remote to the incision site can be recovered from the surgical site, implying that microorganisms located at distant sites could gain entrance to the surgery room.
Microorganisms located at remote sites may infect surgical sites via hematogenous or lymphogenous spread—a likely route of transmission in the neonate but an uncommon route in the adult horse.\textsuperscript{12}

Exogenous microorganisms originate from operating room personnel, contaminated equipment, fluids, the inanimate environment, and the air. The hands of operating personnel contain numerous microorganisms and may be a source of contamination of the surgical site through glove perforations. Therefore, preoperative scrubbing is performed to decrease the number of microorganisms on the hands (see Chapter 11) so that glove perforations do not result in an increased incidence of SSI.\textsuperscript{17}

Other body sites of the surgical team, including the hair, scalp, nares, and oropharynx, are colonized by microorganisms and may serve as a source of SSI. When human albumin microspheres were applied to the head, neck, and inner surface of surgical face masks, they were recovered from the surgical site.\textsuperscript{19} Methicillin-resistant \textit{Staphylococcus aureus} (MRSA), a serious SSI problem in humans, though not considered a very common problem in horses, has been reported to be transmitted from veterinary hospital personnel to equine patients.\textsuperscript{20,21} In humans, MRSA colonization precedes infection, and a major site of human colonization is the anterior nares.\textsuperscript{20}

Microorganisms associated with the inanimate environment of the operating room, including the air, are rarely associated with SSI.\textsuperscript{22} The environment is a potential source of infection when equipment or devices that come into close contact with the surgical site are not adequately disinfected or when there are breaks in aseptic technique.

Microorganisms in the air arise from the patient, the surgical team, and, to a small extent, the inanimate environment. Numerous investigators have studied the effect of airborne transmission in the operating room and the incidence of SSI in human surgical patients. Systems that decrease bacterial counts in the operating room air, including air filtration systems that provide 20 air changes each hour, ultraviolet-irradiated rooms, laminar-flow systems, and surgical team exhaust suits, have not been definitively proven to decrease SSI rates, except in clean orthopedic surgeries such as total hip and knee procedures.\textsuperscript{23-25}

RISK FACTORS FOR SURGICAL SITE INFECTION

Many factors influence the development of SSIs. The development of infection is a function of the interaction between the nature and degree of microbial contamination, the microorganism, local and systemic host defenses, and technical factors that relate to the surgery itself.

Microbe-Related Factors

The isolation of a microorganism from a surgical site may indicate that there is an infection, or the surgical site may be colonized by microorganisms without evidence of infection. Whether particular microorganisms cause infection depends on the interplay among the number of infecting microorganisms, their virulence, and the host's local and systemic defenses.

The critical infective dose of a pure culture of obligate aerobic and facultative anaerobic bacteria has been demonstrated to be \(10^5\) bacteria per gram of tissue or greater; below this concentration, soft tissue wounds heal without evidence of infection. However, \(10^3\) organisms per gram of tissue is a relative number, because SSIs can result from a smaller inoculum if the host's immune response is impaired, a virulent microorganism is involved, or a foreign body is present. Joints are particularly vulnerable to infection, and studies have revealed that only 100 CFU of *S. aureus* need be present for a predictable infection of a synovial joint. Although numerous microorganisms may be introduced into the surgical field at the time of surgery, not all microorganisms are equally capable of causing infection. Established infection depends on an agent's intrinsic capabilities (virulence) to infect and cause disease. The agent must be able to attach to eukaryotic cell surfaces, adapt to its current nutritional environment, multiply sufficiently, and evade the host immune system. Attachment to eukaryotic cell surfaces is mediated by bacterial cell surface adhesions that react with host cell receptors. Some staphylococci, for example, produce a large number of cell-associated and extracellular proteins, including various cytolytic toxins and enzymes such as proteases, lipases, and hyaluronidase that are important for colonization and growth in various body tissues. Microorganisms can evade the host immune response by several means, including possession of an anti-phagocytic capsule that prevents complement deposition on the bacterial cell surface; antigenic variation of cell surface antigens; secretion of IgA proteases at mucosal sites; possession of O-antigen polysaccharide, which resists complement lysis; and being sequestered as an intracellular pathogen.

Microorganisms can evade host defenses and cause infection by adhering to biomaterials such as sutures, prosthetic devices, or bone, resulting in biofilm formation. Biofilms are often polymicrobial in nature but can be caused by a single microorganism. Gram-positive bacteria such as staphylococci produce an extracellular glycocalyx, or mucin, that promotes adherence to biomaterials in greater numbers than gram-negative bacteria. Adherent bacteria form microcolonies that aggregate and produce exopolysaccharides, thus forming an extensive fibrous matrix that mediates their adhesion to each other and to the substrate. The biofilm is resistant to both local and systemic host defenses and antimicrobial agents.
Some microorganisms cause an infection only if another microorganism is present, a phenomenon known as bacterial synergism. Mixed and synergistic surgical infections often contain aerobic and anaerobic bacteria. Interactions among these bacteria may facilitate colonization, lower host resistance, provide nutritional factors, and enhance virulence of one microorganism by another.\(^3\) Some strains of \textit{S. aureus} and \textit{Fusobacterium necrophorum} secrete leukocidins that are cytocidal to phagocytes and protect a mixed inoculum from phagocytosis.\(^{34}\) Bacteria that synthesize \(\beta\)-lactamases or other extracellular enzymes that inactivate antimicrobials can protect otherwise sensitive co-pathogens from these antimicrobials.

**Host-Related Factors**

The quantitative relationship between a host's resistance to infection and the number of bacteria can be altered by both local and systemic factors, including age, weight, metabolic status (see Chapter 5), and presence of remote or distant infections.

**Systemic Risk Factors**

In humans, advancing age is the most important systemic risk factor associated with increasing infection rates. This correlation has not been reported in horses but may become noticeable as treatment of more geriatric equine patients develops. As an example, complication rates of ventral midline incision were lower in horses less than 1 year of age (15\%) than in older horses (43\%).\(^{35}\)

Human patients in shock or severe metabolic derangement are at a greater risk of SSI. Scoring systems are used to index disease severity, and as severity increases, the risk of SSI increases.\(^{40}\) Such scoring systems do not exist in equine surgery, so retrospective studies are confined to comparing surgery performed electively with surgery performed on an emergency basis. The incidence of incisional complication rate for horses undergoing surgery for acute abdominal disease (39\%) was significantly greater than that for those undergoing elective surgical procedures of the abdominal cavity (7\%).\(^{35}\)

Weight and obesity are two important host-related risk factors in humans, where increased weight is often associated with obesity.\(^{15}\) This is not necessarily true in horses because of the differences in weight variations with breed. However, ventral midline incisional complications in horses weighing less than 300 kg (8\%) were fewer than those in horses weighing more than 300 kg (43\%).\(^{35}\) Remote trauma and distant infections have been reported to increase the incidence of SSI by twofold to threefold in humans.\(^{17}\) Local dermatitis or remote infections, such as pneumonia, are always a concern in horses and should be eliminated or controlled to reduce the risk of SSI. Elective procedures should generally be delayed until the infection has resolved. If a remote infection is not controlled, it may develop into a systemic infection. This is usually a greater concern in neonates than in adult horses. At least four mechanisms exist whereby microorganisms may have an effect elsewhere in the body:

1. Bacteremia or septic emboli may result in deposition of organisms in distant tissues.
2. Bacterial toxins can produce cell damage; this is particularly true in hepatocytes.
3. Local necrosis at the site of infection may allow the release of proteolytic enzymes, which facilitate invasion into adjacent regions. Endotoxins and peptidases from injured tissues can activate vasoactive peptides and the clotting and fibrinolytic cascades, cause platelet aggregation, and alter systemic and pulmonary vascular resistance, membrane function, and energy metabolism.
4. Disseminated intravascular coagulation may occur after activation of the clotting cascades, with subsequent platelet consumption, consumption coagulopathy, and accumulation of fibrin-split products (see Chapter 4).

**Local Risk Factors**

Local factors are important when determining the outcome of the interaction between the host and the microorganism. Any foreign body, whether accidental or intentional, inhibits the host's local tissue defenses. The magnitude of this damage appears to be related to the chemical activity of the foreign body. Large numbers of \textit{S. aureus} can be applied to intact skin without resulting in a clinical infection, but if these microbes are injected in the presence of a foreign body such as a suture, only 100 bacteria are needed to cause an infection.\(^{29}\) Soil and dirt are frequent contaminants in traumatic wounds. Specific infection-potentiating factors have been identified in soil, including organic components and inorganic clay fractions.\(^{37}\) Wounds that contain these fractions require only 100 bacteria per gram of tissue to elicit infection. The ability of these fractions to enhance the incidence of infection appears to be related to their damage of host defenses. In the presence of these fractions, leukocytes are not capable of phagocytizing bacteria because of the interaction between the highly charged soil particles and the white blood cells. In contrast, sand grains are relatively innocuous, presumably because of their large particle size and low chemical activity.

**Surgery-Related Risk Factors**

Many factors related to surgery itself have been implicated in increasing the likelihood of SSI. As surgery-related factors can be controlled by the surgeon, this is a method of decreasing the risk of SSI.

**Duration of Surgery**

Longer surgical times are generally associated with a more serious disease or procedure difficulty.\(^{5,36,39}\) Longer procedures require longer anesthesia times, potentially resulting in decreased tissue perfusion, hypoxemia, and hypovolemia as complicating factors that increase the risk of SSI.\(^{17}\) Research has demonstrated clinically and experimentally that the infection rate of clean wounds roughly doubles with every hour of surgery.\(^{40}\) Equine orthopedic procedures taking longer than 90 minutes are 3.6 times more likely to develop SSI than procedures taking less than 90 minutes.\(^{39}\) The number of incisional complications after ventral midline celiotomy is twice as great in operations lasting longer than 2 hours (47\%) than in those lasting less than 2 hours (24\%).\(^{35}\)
The exact mechanism by which prolonged surgical time increases the risk for SSI is unclear. Four possible explanations have been considered:

1. An increase in contamination of the wound
2. An increase in tissue damage because of drying, prolonged retraction, and manipulations
3. An increase in the amount of suture and of electrocoagulation, which may reduce local resistance
4. Greater host defense suppression because of blood loss and shock

To avoid prolongation of operating time, the surgeon should have a working knowledge of the local anatomy and, when possible, should practice on a cadaver specimen prior to operating on a patient.

**Patient and Surgeon Preparation**

Studies that have evaluated the effects of various equine patient preparation techniques on SSI are lacking. However, the use of antiseptics to prepare the skin of horses significantly decreases the number of skin bacteria. The use of antiseptics in preparing both patient and surgeon decreases the incidence of infection (see Chapters 10 and 11). In people, there is a marked increase in SSI after shaving compared with the use of clipping or depilatories, especially when shaving was done the night before the surgical procedure. Shaving disrupts the skin barrier through microtrauma or lacerations of the surgical site, thus predisposing the patient to SSI. If shaving is performed, it should be completed just before surgery to prevent microbial colonization.

There are several time-honored practices in surgeon preparation, including hand hygiene and the wearing of masks, caps, gowns, and gloves. Many of these practices have been traditionally believed to decrease the incidence of SSI and are considered a gold standard in today’s veterinary hospital, even if few are supported by well-designed clinical studies. Even simple procedures such as the use of double gloves can decrease the incidence of infection. Double gloving should be employed in all orthopedic operations involving fracture manipulation because of the high risk of perforation. We do not advocate double gloving for all surgical procedures, but we routinely double glove during the draping procedure because this is commonly where a break in asepsis occurs. The outer gloves are shed prior to the skin incision, or if double gloving will be used throughout the operation, the outer gloves are then changed. Studies show that frequently changing outer gloves during surgery is an effective method of minimizing contamination.

**Surgical Technique**

The surgeon’s skill has a central role in SSI. The risk of infection is decreased by adhering to Halsted’s principles of minimizing hemorrhage and tissue trauma; using correct instrumentation, suture materials, and implants; débriding devitalized tissue; and eradicating dead space. Débridement is the most important factor in the management of a contaminated or infected wound. Débridement removes tissue heavily contaminated by soil, infection-potentiating factors, and microorganisms. It also removes devitalized soft tissues that would alter host defenses and encourage the development of infection. Devitalized tissue enhances infection by acting as a culture medium for bacterial growth, inhibiting leukocyte phagocytic activity, and creating an anaerobic environment.

**INCISION**

The skin incision can be made by three techniques: (1) stainless steel scalpel, (2) electrosurgery, or (3) laser. It is reported that skin incisions made by either electrosurgery or laser have a threefold to 10-fold greater incidence of susceptibility to infection than those made by a stainless steel scalpel. This is probably because of the increase in lateral thermal necrosis observed when using electrosurgery and lasers. However, in cases requiring massive excision, the risk of blood loss frequently outweighs the potential problem of subsequent infection. In addition, equine abdominal surgery that requires approaches through the muscular body wall (flank incisions) have a greater incidence of SSI than those through the ventral midline (88% versus 29%, respectively). The increased incidence of infection after flank incisions is believed to be caused by an increase in dead space and muscle necrosis from excessively tight sutures or muscle trauma during surgery.

**SUTURE MATERIALS AND SURGICAL IMPLANTS**

Devices placed in or under the skin through surgical intervention may also increase the incidence of surgical infection by acting as a foreign body and altering local tissue defense mechanisms. Bacteria adhere to these devices and proliferate to form a biofilm. Typically, in equine surgery, these are orthopedic devices (screws, wires, plates) or mesh implants. Sutures, particularly nonabsorbable suture materials, should also be considered as a potential source of infection or sinus tract formation. The use of polyglactin 910 to close the linea alba in horses was significantly associated with increased risk of postoperative wound infection, compared with the use of polydioxanone and polyglycolic acid.

**Length of Hospitalization**

In humans, a prolonged preoperative hospital stay is highly associated with incisional infection. A prolonged stay can promote the proliferation of endogenous or hospital-acquired microorganisms. Hospitalization length is often not reported in equine studies on SSI, but it should be considered as advanced procedures and hospitalized recuperation become more common.

**NOSOCOMIAL INFECTION IN THE SURGICAL PATIENT**

Hospital-acquired or nosocomial infections are defined as infections acquired within a hospital or clinic that were not present or incubating at the time of admission. The majority of nosocomial infections become clinically apparent while patients are still hospitalized, often after 48 hours of hospitalization. Infections that develop after hospital discharge are also considered nosocomial if there is a direct link between the infection and the hospitalization.
It has been estimated that 5.7% of human patients admitted to acute care hospitals in the United States develop nosocomial infections. Furthermore, approximately 24% of these nosocomial infections are SSIs. However, this percentage may actually underestimate the true occurrence of SSIs, because 20% to 80% of postoperative infections become clinically apparent only after hospital discharge, and studies often do not include surveillance after hospital discharge.

Published surveillance studies of nosocomial infection rates in veterinary medicine are limited. However, one report determined that 21.9% of 105 hospitalized horses developed nosocomial gram-negative aerobic infections by other than Salmonella species, and of these infections, 48% were postoperative SSIs. Salmonella appear to be one of the most common causes of nosocomial infections in horses. Salmonella species have been reported to cause hospital outbreaks of infection in horses, with surgery and antimicrobial therapy being important risk factors. Horses may be asymptomatic carriers and shed the organism for weeks or months and serve as a significant reservoir of infection for both patients and personnel. However, determining whether an infection caused by Salmonella is nosocomial or the result of a preexisting latent infection may be difficult. Other gram-negative rods, such as E. coli and species of Pseudomonas, Enterobacter, Citrobacter, Proteus, and Klebsiella, have been reported to cause nosocomial infections in horses. Gram-negative rods colonize patients and survive well in the hospital environment, thriving in minute traces of moisture with minimal nourishment, and in the presence of proteinaceous material, they resist desiccation. Other bacteria reported in equine nosocomial infections include gram-positive bacteria and anaerobes such as Clostridium difficile. Bacterial organisms are the most frequently involved in nosocomial infections, but other microorganisms, including viruses, Chlamydia, Mycoplasma, fungi, and protozoa, can also cause nosocomial infections.

Nosocomial infections contribute to increased morbidity, prolonged hospitalization, adverse patient outcome, and increased patient care cost. Approximately 2.5 million human nosocomial infections occur each year, costing the U.S. healthcare system over $10 million. Although hospital epidemics or outbreaks are frequently reported in the literature, the majority of nosocomial infections are endemic. Nosocomial infections are frequently caused by the normal microorganisms colonizing the patient at the time of admission or by exogenous, hospital-associated microorganisms that are acquired and subsequently colonize the patient after admission. Colonization of the skin, mucosal membranes, or any other site is an important step before infection; however, whether infection and disease occur depends on interactions between the infecting organism and the host.

Surgical patients are at risk for the development of nosocomial infections. Surgical procedures, surgical implants, and invasive devices such as intravascular catheters, indwelling urinary catheters, and nasogastric and endotracheal tubes compromise the host’s normal anatomic epithelial and mucosal antibacterial barriers. Surgical patients receiving antibiotic therapy risk nosocomial infections because the antibiotics alter the normal microbial ecology of the patient’s skin; upper respiratory, gastrointestinal, and urogenital tracts; and any other site typically colonized by microorganisms. Maintenance of the patient’s normal microbial ecology is a potent deterrent to colonization by nosocomial pathogens.

Common types of nosocomial infections that occur in surgical patients include urinary, lower respiratory tract, and hematogenous infections, but SSI is the most common. Nosocomial SSIs are usually the result of the patient’s endogenous or hospital-acquired flora. Infections caused by exogenous sources of microorganisms are a result of direct or indirect contamination of the surgical site by operating room personnel, contaminated devices or fluids, and, occasionally, airborne transmission of microorganisms from members of the operating room team. Outbreaks resulting from nosocomial pathogens occur principally via transmission from colonized or infected patients to other patients via the transiently colonized hands of personnel, who acquire the microorganisms after direct patient contact or after handling contaminated materials. Transmissions via contaminated equipment, devices, solutions, air, or the inanimate environment occasionally occur.

Increasingly, more nosocomial pathogens cultured from patients postoperatively and from the hospital environment are resistant to antibiotics. Antibiotic resistance is a consequence of selective pressure from their use. Antibiotic pressure can cause susceptible strains to become resistant through mutation or through the acquisition of resistance genes, or it can provide a selective advantage for the emergence of resistant bacterial strains already present but in small quantities. Patients colonized by drug-resistant bacteria serve as a reservoir of these microorganisms and of transferable antibiotic resistance determinants that can be further transferred to susceptible bacteria.

Prevention and control of nosocomial infections are directed at elimination or containment of reservoirs, interruption of infection transmission, and protection of patients, personnel, and visitors from nosocomial infection and disease. A nosocomial infection control program that includes barrier precautions, isolation precautions, disinfection, and sterilization protocols is important in veterinary medicine for the control of nosocomial infections. Hand disinfecting is the most effective method of preventing nosocomial infections. Monitoring of antibiotic resistance patterns and programs directed at controlling antibiotic use are also important in veterinary medicine if the emergence of antibiotic resistance is to be controlled. Surveillance of surgical patients for nosocomial infections using standard definitions is important to determine endemic rates of infection, to aid in identification of outbreaks, to identify new nosocomial pathogens, and to recognize and alter hospital practices that may contribute to nosocomial infections.

**PREVENTION AND MANAGEMENT OF SURGICAL SITE INFECTIONS**

Most publications dealing with postoperative infection rates of equine patients contain data on specific conditions rather than being overall reviews (Table 7-4). Two trends appear from examining these studies. Infection is uncommon in elective general surgery and rarely results in mortality, whereas orthopedic procedures, particularly those

involving fracture fixations, have greater rates of infection and mortality. The seriousness of orthopedic infection in the horse is emphasized by a retrospective study that demonstrated a 36% rate of euthanasia because of uncontrolled orthopedic infection, and a resolution of infection in only 48% of horses treated, even after implant removal.84

The cost of SSI in horses has not been calculated. However, the mean duration of hospitalization of 25 horses with postoperative septic arthritis was 39 days (range, 6 to 125 days).85 Therefore, even conservative daily costs would result in a high total treatment cost. Additionally, treatment of infection after internal fixation can be devastatingly expensive, and treatment of many other SSIs in the horse can be similarly costly.

Evaluation of large numbers of human patients has allowed physicians to determine infection rates after surgery and establish risk factors.40-42 This information can be combined with equine postoperative infection rates to propose guidelines for the reduction of postoperative infection in horses; however, not all information from human studies is applicable. The reasons for different infection rates and outcomes after infection in horses compared with humans have yet to be entirely identified. However, equine surgeons encounter challenges that are not present in surgery on humans, and they affect equine postsurgical infection rates. Some disparities most likely result from environmental differences—for example, horses are "hospitalized" in a barn stall, not in a hospital bed. The amount of contamination to a traumatic wound or open fracture is likely to be more significant in horses because of these environmental conditions, which increase the likelihood of developing an SSI.

Diagnosis of Surgical Site Infections

Clinical Signs

Clinical diagnosis of SSI can be challenging. Uninfected and grossly infected wounds are easily identified, but mild to moderate infections may be more difficult to identify.30 Postoperative fever is one of the earliest and consistent signs of an orthopedic SSI,31 but it can be the result of other sources of inflammation, such as respiratory or gastrointestinal tract conditions. Superficial and deep incisional wounds are considered infected when one or more of the following is present: (1) discharge of purulent material, (2) spontaneous dehiscence of one or more wound layers, accompanied by serous drainage, (3) organisms isolated from an aseptically obtained culture of the area, or (4) excessive erythema, pain, or swelling in the immediate postoperative period.30-32 The most common superficial SSI in the horse is infection of the ventral midline incision after an emergency celiotomy. The first clinical signs of infection are excessive edema, pain elicited with digital palpation, and an accumulation of serous or exudative fluid revealed by palpation of the incision.

Recognition of organ or space infections can be more difficult. The first clinical signs often seen in horses with osteomyelitis and septic arthritis are excess fluid accumulation in the surgical site.32 Lameness is another early clinical signs of an orthopedic SSI. However, if lameness was present before surgery, it can be difficult to differentiate a lameness caused by infection from the preexisting lameness.

Because of their remote locations, organ or space infections often require laboratory evaluations of fluid or tissue, or diagnostic imaging, for confirmation.

Laboratory Evaluations

The goal of a laboratory evaluation is to distinguish between posttraumatic or postsurgical inflammation and postsurgical infection. Complete blood counts may be useful but can be within normal limits in the presence of infection. Wound fluid can be obtained from superficial and deep incisional infections after surgical drainage or spontaneous dehiscence. Although cytologic examination of incisional fluid is not commonly performed, it should be cultured to help direct antimicrobial therapy.

Cytologic examination of fluid obtained from a potential infection of an organ or space is valuable in determining if infection is present. Normal postoperative values for peritoneal fluid after laparotomy are available,33 but similar values are not available for joints. However, laboratory findings on examination of space fluids that indicate infection include increases in both number and concentration of polymorphonuclear leukocytes, an increase in the total protein concentration, and evidence of bacteriophobia by inflammatory cells. Correct interpretation of the results requires knowledge of the cytologic changes that result from surgery alone. Even with this information, these values may be confusing after abdominal surgery when the results are equivocal and the results of bacterial culture of peritoneal fluid are pending. Recently, a study indicated that peritoneal fluid pH and glucose concentration can be used to assist in the identification of horses with postoperative septic peritonitis. The finding that the difference between the glucose concentration in serum and that in peritoneal fluid is pending. Recently, a study indicated that peritoneal fluid pH of less than 7.3, a glucose concentration of less than 30 mg/dL, and a fibrinogen concentration of greater than 200 mg/dL were also highly indicative of septic peritonitis after an exploratory celiotomy.34 Nonetheless, clinical evaluation is often the best early indicator of SSI, and treatment should begin when clinical signs are noted. Animals with acute peritonitis are characterized by shock, ileus, abdominal distention, and nasogastric reflux. The animal may be febrile, have a slow capillary refill time, and show evidence of hemocoagulation and leukopenia on a complete blood count. Plasma protein may decline because of its effective loss from the circulation into the peritoneal cavity. Therapy should not be delayed until "conclusive" evidence of infection, such as positive cultures or evidence of degenerative neutrophils in surgical site fluid, is identified.

Osteomyelitis is a serious organ infection in equine surgery because of the fatality rate associated with this infection. Osteomyelitis can (1) be hematogenous in origin, which is common in foals but rare in adults, (2) spread from an adjacent infected soft tissue focus, (3) occur as the result of a penetrating wound, or (4) occur secondary to surgery for fracture repair. Postoperative osteomyelitis may be difficult to diagnose if no accumulation of fluid is apparent. However, if it is present, fluid accumulation should be sampled percutaneously after sterile preparation of the skin, and a finding of greater than 90% neutrophils in the fluid...
suggests that infection is present. If spontaneous drainage occurs, culture of the draining tract may be useful to identify the pathogen. Enrichment media (blood culture, thiglycolate broth) are generally not recommended, as contaminants or other local nonprincipal pathogenic organisms may have their growth enhanced as well, to the exclusion of the principal pathogen.

**Imaging Techniques**

Radiography of the surgical site is the most commonly used tool for the diagnosis of osteomyelitis, but it is not particularly sensitive, especially for early diagnosis. Initial radiographic changes result from hyperemia and bone demineralization, but 50% to 75% of bone mineral must be lost before this change can be seen on plain radiographs. Therefore, radiographic signs of infection in bone are not usually apparent for at least 7 to 10 days after the onset of symptoms and can take as long as 3 weeks. With chronic infection, radiographic lucencies associated with areas of bone lysis predominate, and radiodense bone sequestra can form. These sequestra may become surrounded by an envelope of proliferative periosteal new bone growth, known as an involucrum.

Alternatively, ultrasonography has been used to diagnose osteomyelitis in human patients and osteitis in equine patients. Further work is needed regarding the use of ultrasonography in the early diagnosis of bone or implant infection in horses. However, this technique is invaluable in the evaluation of equine ventral midline incisions. Nuclear scintigraphy using technetium-99m diphosphonate is a very sensitive indicator of bone turnover and can yield positive signs of osteomyelitis 10 to 14 days before radiographic signs are observed. However, a positive bone scan is not specific for infection, and scintigraphy is nonspecific in cases of recent wounding and fracture development, or when recent surgery has occurred. Computed tomography and magnetic resonance imaging have certain specific indications in the diagnosis of osteomyelitis in human patients. As these imaging modalities, especially magnetic resonance imaging, become more available in veterinary hospitals, their role in diagnosing soft tissue infections and osteomyelitis should become more significant.

**Prevention of Surgical Site Infections**

The identification of preoperative, intraoperative, and postoperative factors that contribute to SSI pathogenesis has led to several interventions that may be applied to decrease the risk of SSI. These interventions include practices that have been scientifically proven in the horse to decrease the risk of SSI, as well as those that may theoretically decrease the risk of occurrence. Programs for surveillance of SSIs in human patients that include feedback and intervention measures and the evaluation of their efficacy. identified, and therefore hospital surveillance programs should be implemented.

**Surveillance**

An essential part of an effective infection control program is SSI surveillance, which entails the ongoing systematic collection, analysis, and interpretation of data relating to the frequency and distribution of SSI and the conditions that increase or decrease its risk of occurrence. Programs for surveillance of SSIs in human patients that include feedback of SSI rates to surgeons have been reported to decrease the incidence of infections. Surveillance identifies endemic rates of infection and, once established, can result in a more rapid recognition of an outbreak. Identifying risk factors that contribute to SSI allows the institution of appropriate intervention measures and the evaluation of their efficacy. Essential components of a surveillance program include established criteria for the definition of SSI, critical eval-
Pathogenic Bacteria Associated with Equine SSI

The organisms most commonly associated with equine orthopedic SSI are Enterobacteriaceae, *Pseudomonas*, *Streptococcus*, *Staphylococcus*, and anaerobes. Two studies on orthopedic SSI reported 60% and 19% polymicrobial infections, respectively. The second striking difference is the 18% incidence of staphylococcal isolations in the first study, whereas in the second study, 52% of the isolates were staphylococcal. The differences between these studies were probably caused by the different sites of infection surveyed. The first study examined only orthopedic procedures, whereas the second study examined cases with septic arthritis and tenosynovitis. Fractures tend to become infected with multiple gram-negative bacteria, whereas septic arthritis is often the result of an iatrogenic inoculation with *Staphylococcus* species. These two studies show that gram-negative and gram-positive aerobic bacteria and anaerobic bacteria all have the potential to cause an equine orthopedic SSI. It is also suggested that nonarticular orthopedic infections should be considered polymicrobial until proven otherwise, and that postoperative septic arthritis is often caused by *Staphylococcus* species. Both studies note that not all patients were cultured for anaerobes, and therefore the incidence of anaerobic infection may be underrepresented.

**Reduction of Bacterial Numbers in the Surgical Site**

Proper design and maintenance of the surgical suite is important in the reduction of overall bacterial numbers, as is appropriate antiseptic preparation of the surgical site, including the clipping of hair. Removal of devitalized tissue, removal of foreign substances, and wound lavage decreases the number of bacteria in contaminated surgical sites and also reduces SSIs. Postoperative wound contamination can also be reduced by keeping a sterile dressing on the surgical site until healing has occurred.

**Antibiotic Prophylaxis against Surgical Site Infections**

**PERIOPERATIVE ANTIBIOTIC THERAPY IN HORSES**

Antibiotic therapy constitutes a major component of SSI prophylactic regimens for horses undergoing elective and emergency surgical procedures. Development of an effective and safe antibiotic regimen requires knowledge of their mechanism of action, their toxic side effects, their pharmacokinetics, and other important principles regarding prophylaxis.

**ANTIBIOTIC CLASSIFICATION**

Antibiotics can be classified as bactericidal versus bacteriostatic, as broad-spectrum versus narrow-spectrum, and by their mechanism of action. Mechanisms of action include inhibition of cell wall synthesis, reversible or irreversible inhibition of protein synthesis, inhibition of plasma membrane function, inhibition of nucleic acid synthesis, and inhibition of intermediary metabolism (Table 7-6). Classifying antibiotics according to their mechanism of action is useful because the mechanism does not change from patient to patient, concurrent use of more than one antibacterial agent can result in altered susceptibility patterns.

drug can be rationally formulated, the mechanisms of bacterial resistance are easily understood, and it helps predict or explain toxic or adverse effects. 109

PROPHYLACTIC VERSUS THERAPEUTIC ANTIBIOTICS
Antibiotics administered for prophylaxis differ from those administered for therapeutic purposes. Antibiotics are administered therapeutically when an infectious process is already present. Prophylactic antibiotics are typically administered perioperatively in horses undergoing surgical procedures. The principles of these two uses differ. Antibiotics used for prophylaxis should always be bactericidal and must be administered so that they reach the surgical site in sufficient concentrations at or before the time of the procedure to prevent establishment of infection. Moreover, to decrease the development of bacterial resistance to the antibiotics necessary to treat serious, life-threatening infections, prophylactic antibiotics should not be the same ones typically used to treat established infections. Because there have been limited reports of controlled studies regarding the efficacy of prophylactic antibiotics in horses, 111 most recommendations are based on extrapolations from human studies. The risk of SSI must outweigh the potential adverse effects to warrant the use of prophylactic antibiotics. Most of the risk of SSI in veterinary medicine is related to the skill of the surgeon and thus the duration of the surgery, as well as to the management practices of the hospital. 112 Antibiotic prophylaxis is most effective when administered within 1 hour of bacterial inoculation, and it is ineffective when administered 3 to 4 hours after bacteria inoculate the wound. 70, 113

Guidelines have been established for the use of antibiotic prophylaxis. 70, 113 Antibiotics should be used only for procedures with a high likelihood of postoperative infection. Peak serum concentrations of the antibiotics should reach 4 to 8 times the minimum inhibitory concentration (MIC) for bacteria being treated. The antibiotics should achieve adequate tissue levels throughout the duration of the procedure. Effective antibiotics that are least cytotoxic and least costly should be used. Timing of antibiotic administration should permit absorption and distribution to the target tissue, without promoting bacterial resistance. This usually means intramuscular administration of antibiotics 1 to 2 hours before surgery or intravenous administration immediately prior to the time of induction of general anesthesia (approximately 30 to 60 minutes prior to surgery). Recent trials in humans have suggested that a single dose of an appropriate antibiotic regimen 30 to 60 minutes before surgery provides adequate prophylaxis; a second dose is given for procedures lasting longer than 3 hours. 30 There is no apparent benefit to continuing antibiotic prophylaxis for more than 24 hours postoperatively. Therefore, prophylactic antibiotics should generally not be administered for more than 24 hours and definitely no longer than 72 hours. 113 In veterinary medicine, a single preoperative dose is usually sufficient and is more cost effective. 114 If infection develops despite prophylactic antibiotics, the bacteria should be considered resistant. Prolonged administration of prophylactic antibiotics could contribute to the occurrence of adverse effects and might promote the development of resistance.

Prophylactic systemic administration of antibiotics is indicated for all clean-contaminated and contaminated surgical wounds, for clean surgical wounds involving an implant or prosthesis, and for any situation in which development of an infection is considered life threatening. 70, 113 Systemic prophylactic antibiotics are also indicated for high-risk patients, animals suffering from a concurrent disease process, animals appreciably underweight or malnourished, animals advanced in age, and possibly animals receiving corticosteroids. Because the infection rate for clean surgical wounds is quite low, systemic antibiotic prophylaxis is generally not needed and may be contraindicated in these procedures. There is much disagreement about indications for systemic prophylactic antibiotic treatment of clean-contaminated surgical procedures. 70, 113 Because all procedures involving entry into the upper respiratory, urogenital, and gastrointestinal tracts carry an increased risk of infection, many clinicians recommend the use of prophylactic antibiotics. The decision to administer prophylactic antibiotics should be made individually, taking into account the probable magnitude of contamination, the patient’s immune status, and the length of the procedure. If major spillage or contamination is possible, then prophylactic antibiotics are indicated. Systemic antibiotics are mandatory for contaminated and dirty procedures. 70, 113 It must also be remembered that antibiotics are often administered prophylactically to horses undergoing general anesthesia and surgery, to prevent pneumonia and pleuropneumonia. The most commonly used antibiotics for systemic prophylaxis in horses includes a combination of penicillin and gentamicin, penicillin alone, trimethoprim-sulfonamides, or cefotiofur.

Topical antibiotics can also be used prophylactically. 70 Some studies have shown that topical antibiotics have a significant advantage over placebo administration. When systemic antibiotic prophylaxis is compared with topical antibiotics, there is no appreciable difference in the rate of SSI. Concurrent use of systemic and topical prophylactic antibiotics has no greater efficacy in preventing infection over either one alone. When topical antibiotics are used, results are optimal when the antibiotic is administered immediately after opening each tissue plane; this prevents bacterial adherence to tissue. Irrigation of the tissues with the antibiotic should continue throughout the surgical procedure, not simply prior to closure. The antibiotics that have been used for topical wound irrigation include penicillin, kanamycin, lincomycin, cephalothin, ampicillin, and a combination of neomycin, bacitracin, and polymyxin B. 70

SELECTION OF PROPHYLACTIC ANTIBIOTICS
Selecting an antibiotic is an important decision for the prophylaxis of SSI in horses. Knowledge of the most common bacteria isolated from horses with infections involving different sites and their probable antibiotic susceptibility patterns is necessary. Clinical experience and the results of retrospective studies evaluating antibiotic susceptibility patterns of equine bacterial pathogens should assist clinicians in making rational choices regarding antibiotic treatment, both for established infections and for prophylactic use during surgical procedures. 70, 109, 110, 113, 115 As an example, Enterobacteriaceae, staphylococci, streptococci, and Pseudomonas species represent 69% to 77% of the organisms isolated from infected orthopedic procedures. 113, 78 Currently, there are no published data regarding the most common bacteria isolated from surgical sites after...
GENERAL SOFT TISSUE SURGERY. Surgeons should be familiar with the most likely bacteria involved in SSI and the likely antibiotic susceptibility patterns in their own hospitals or practices.

Numerous factors should be considered when selecting an antibiotic regimen in horses.70,101,103 These include the presence or likelihood of an infectious process, the type of infectious process, the most likely bacteria to be isolated, the age and immune status of the animal, the cost of antibiotics, the ease of administration, and potential toxic side effects. The type of established or likely infectious process is important when selecting an antibiotic regimen. Some infections such as septicemia require immediate, aggressive treatment because the infection may be life threatening. On the other hand, a chronic infectious process is usually not immediately life threatening, and therefore a more thorough diagnostic evaluation can be performed prior to initiating antibiotic therapy. Selection of an appropriate antibiotic regimen in these cases usually necessitates knowledge of the most likely organisms to be involved in the infection and the probable susceptibility patterns of these isolates; this is often based on practical experience or retrospective studies. Infectious processes unresponsive to initial antibiotic treatment or complicated infections necessitate identification of the offending bacteria and determining their antibiotic susceptibility pattern. Undoubtedly, refinement of bacterial isolation and identification techniques and antibiotic susceptibility testing has dramatically improved the ability of clinicians to select appropriate antibiotics.

It is generally believed that prophylactic antibiotics are not necessary for horses undergoing routine arthroscopic procedures that do not involve the use of implants. This is because of the extremely low infection rate reported following these procedures, which probably results from the minimal surgical wound area and the continuous lavage of the joint with a large volume of fluid. However, certain factors may necessitate the need for prophylactic antibiotics, such as the intraarticular administration of corticosteroids in the recent past. Similarly, antibiotics are probably not necessary for routine laparoscopic procedures such as an ovariectomy and cryptorchidectomy. Prophylactic antibiotics are often indicated in horses undergoing other types of articular surgery because of the potentially devastating consequences of septic arthritis. When a synovial structure becomes infected postoperatively, staphylococci are commonly isolated, which suggests that an antibiotic effective against staphylococcal species should be chosen.78 Depending on the results of antibiotic susceptibility testing of bacteria isolated from horses with postoperative orthopedic infections, an aminoglycoside, a cephalosporin, or both have been recommended.13 Although it has been reported that amikacin is the most effective antibiotic presently available to treat orthopedic infections in horses, it should probably not be used for routine prophylaxis because of the possibility of promotion of antibiotic-resistant strains. Rather, gentamicin is probably more appropriate in this situation, depending on other factors including whether or not implants are involved and the nature of the fracture (open versus closed) or injury.

The risk of potential side effects of an antibiotic must be considered when selecting a prophylactic antibiotic regimen. Horses appear to be susceptible to antibiotic-associated diarrhea, apparently secondary to disruption of the gastrointestinal tract microflora.116 Antibiotics have been shown to promote the overgrowth of opportunistic bacteria, select for resistant strains, and disrupt bacteria that contain toxins.117 Although the causal relationship between the administration of antibiotics and diarrhea in horses is poorly understood, anecdotal experience suggests that caution is warranted when selecting prophylactic antibiotics. For example, orally administered antibiotics and administration of antibiotics to highly stressed or anorexic horses should be carefully considered.

ANTIBIOTICS USED FOR PROPHYLAXIS IN HORSES
Penicillin G remains one of the most effective antibiotics for prevention and treatment of certain bacterial infections in horses.115 The mechanism of action involves interference with synthesis of the bacterial cell wall peptidoglycans, resulting in cell lysis in a hypoosmotic or isoosmotic environment. Penicillin is effective against most β-hemolytic streptococci, β-lactamase-negative staphylococci, and obligate anaerobes other than Bacteroides species. Penicillin G is easily inactivated by β-lactamas and has little efficacy against bacteria that can produce these enzymes. It is most useful for the prevention or treatment of β-hemolytic streptococci and anaerobes. Penicillin G is administered either via the intramuscular route as procaine penicillin G or intravenously as the potassium or sodium salt.

Aminoglycosides, particularly gentamicin, are commonly administered for antibiotic prophylaxis. Aminoglycosides are actively pumped into the interior of bacterial cells, where the drug binds to the 30S ribosomal subunit and causes a misreading of the genetic code, interrupting normal bacterial protein synthesis.118 This interruption in protein synthesis leads to alterations in cell membrane permeability, additional aminoglycoside uptake, additional bacterial cell disruption, and ultimately cell bacterial death. Aminoglycosides exert an effect even after administration has ceased. They are effective against most gram-negative bacteria, including Pseudomonas, and they are somewhat effective against staphylococci. Streptococci are often resistant, and because aminoglycosides move into bacterial cells via an oxygen-dependent pump, these drugs are not effective against anaerobic bacteria. Gentamicin and amikacin are the most commonly used aminoglycosides. Gentamicin should probably be used for short-term prophylaxis and amikacin reserved for longer-duration therapeutic use. Amikacin is effective against bacteria that are often resistant to other aminoglycosides, because it is more resistant to bacterial enzymatic inactivation.

Cephalosporins, which inhibit bacterial cell wall synthesis, are sometimes used for prophylaxis, particularly in horses undergoing orthopedic procedures. Cefotiofur, a new-generation cephalosporin, is used in some hospitals for routine antibiotic prophylaxis. It is active against many bacterial pathogens commonly isolated from horses, including streptococci, Pasteurella species, obligate anaerobes, and some staphylococci and Enterobacteriaceae. Pseudomonas species are usually resistant.119 Cefotiofur is rapidly metabolized to the active metabolite desfuroylcefotiofur; however, the metabolite is less effective against S. aureus and Proteus species. It is important to know whether the microbiology
laboratory uses cefiotaur or desfuroylceftiofur discs for susceptibility testing, as desfuroylceftiofur results for staphylococci and Proteus may not be reliable for predicting efficacy of cefiotaur against these bacteria. Cephalosporins should probably be administered intramuscularly because of their rapid elimination after intravenous injection.

Potentiated sulfonamides are usually formulated at a ratio of 1:5 with trimethoprim. Sulfonamides inhibit the bacterial dihydropteroate synthetase in the folic acid pathway, thereby blocking bacterial nucleic acid synthesis. Sulfonamides substitute for para-aminobenzoic acid (PABA), which prevents its conversion to dihydrofolic acid. When used alone, sulfonamides are bacteriostatic. However, in combination with trimethoprim, they inhibit successive steps in the folic acid pathway, so the combination is bactericidal. Trimethoprim inhibits bacterial folic acid synthesis at the next step in the folic acid pathway, inhibiting the conversion of dihydrofolic acid to tetrahydrofolic acid by inhibiting dihydrofolic acid reductase. Sulfonamides have a relatively broad spectrum of activity and are typically effective against streptococci, Proteus, E. coli, Pasteurella, and Salmonella. Staphylococci, obligate anaerobes, Klebsiella, and Enterobacter are usually susceptible, but they may develop resistance. On the other hand, Pseudomonas species are usually resistant.

TIMING AND DURATION OF ANTIBIOTIC ADMINISTRATION

Prophylactic antibiotics should be administered before the surgical procedure to exert their maximal effect. Although a transient decrease in arterial blood pressure has been reported after the IV administration of sodium penicillin in horses, we believe that penicillin can be used safely in horses when given shortly before anesthetic induction. Evaluation of the horse’s heart rate after IV penicillin administration prior to anesthetic induction is recommended. Depending on the length of the surgical procedure and the pharmacokinetcis of the given antibiotic, intraoperative redosing may be necessary to maintain high circulating and tissue concentrations of antibiotic.

Much controversy exists over the appropriate duration of prophylactic antibiotic administration. In humans, there is probably no additional benefit after 24 hours of prophylactic antibiotics. Furthermore, it has been demonstrated that a single prophylactic dose of antibiotic(s) results in wound infection rates that are similar to the rates obtained with multiple dosing regimens. Despite this finding, antibiotics are often administered prophylactically for extended periods. There is substantial variability in the duration of prophylactic antibiotic administration used by different equine surgeons. Generally, the duration of administration for antibiotic prophylaxis should not exceed 24 hours in horses; however, antibiotics are often administered for up to 24 hours after removal of a surgical drain. This is important because surgical drains are often used with orthopedic procedures, and orthopedic infections are often polymicrobial in nature, which suggests that environmental contamination contributes to these orthopedic infections. Because of the devastating effects of implant-associated infection in orthopedic procedures, many equine surgeons administer prophylactic antibiotics for several days after fracture fixation. The duration of antibiotic administration often depends on the nature of the injury or wound; the length of the surgery; the health of the overlying soft tissues; other factors related to the bacteria, host, and surgery; and the surgeon’s preference.

The optimal duration of antibiotic prophylaxis for emergency gastrointestinal tract surgery has not been determined in horses. Because there is a relatively high prevalence of SSI in horses after emergency abdominal surgery, surgeons often choose to administer antibiotics for a longer duration than for many other surgical procedures. However, as there have been relatively high rates of infection in horses receiving prophylactic antibiotics, they may not be particularly efficacious. The duration of antibiotic administration in these horses depends in large part on the diagnosis, and on the presence and magnitude of contamination. Horses with gastrointestinal tract ischemia and those requiring an enterotomy or resection and anastomosis may need to have prophylactic antibiotics administered for a longer period of time. The surgeon determines when to discontinue antibiotic administration in these horses, and the decision should be based on rectal temperature, appearance of the surgical site, and the complete blood count and fibrinogen concentration.

SPECIAL ROUTES OF ADMINISTRATION AND DOSAGES

Topical administration of antibiotics is useful prophylactically to prevent intraoperative wound infections, and it is used in irrigation fluids during surgical débridement and repair of contaminated wounds. The triple antibiotic combination of neomycin, bacitracin, and polymyxin B is recommended. Silver sulfadiazine is a useful topical antibiotic for the treatment of wound infections caused by Pseudomonas. The addition of Tris-EDTA to an aminoglycoside such as gentamicin for topical administration increases its effectiveness against Pseudomonas by altering the cell membrane and making it more permeable to the aminoglycoside.

Intrathecal administration of gentamicin (150 mg per joint) or amikacin (250 to 500 mg) have been shown to result in synovial fluid concentrations that remain above the MIC of most pathogenic bacteria for 24 hours or greater. The advantages of intra-articular antibiotics are that a lower total dose of antibiotic can be used (thus less expensive), and a greater concentration of antibiotic will be maintained in the synovial fluid for a longer period of time than with parenteral administration. Although used most frequently to treat infected joints and tendon sheaths, antibiotics can be injected into synovial structures to prevent perioperative infection at the conclusion of joint or tendon sheath surgery.

Regional limb perfusion with antibiotics has been used experimentally and clinically in horses. This method involves the delivery of antibiotic under pressure to a selected region of the limb through the bone or venous system. This is an effective method of delivering high concentrations of antibiotics to bones, joints, and tendon sheaths. Although this route is often used therapeutically to treat orthopedic infections, it can be used intraoperatively or perioperatively to prevent infection. The antibiotic can be delivered via an intravenous catheter or a butterfly catheter placed in a superficial vein, or through a catheter adapter placed in a 4.5-mm hole drilled in the bone. The limbs are usually wrapped tightly with an Esmarch bandage distal to
the entrance of the venous system and proximal to the site of infection to occlude the superficial venous system and open the collateral osseous venous circulation. Perfusion rates are usually administered over a period of approximately 30 minutes at a maximal perfusion pressure of 450 psi. Once the infusion is completed, the Esmarch bandage and catheter are removed (see Chapter 88).

Antibiotic-impregnated plaster of Paris (POP) or polymethylmethacrylate (PMMA) has been used successfully in horses for prophylaxis and treatment of musculoskeletal infections.86,129 Eighty percent of gentamicin is eluted from POP beads within the first 48 hours after implantation, but it continues to be eluted at concentrations deemed bactericidal for 14 days.129 The gentamicin also retains its bactericidal activity after ethylene oxide sterilization and storage at room temperature for up to 5 months. PMMA is a high-density plastic formed by combining a fluid monomer and a powdered polymer; the antibiotics are added to the PMMA as it is being mixed, and they become suspended in the PMMA. During the hardening process, the PMMA is molded into round beads or cylinder-shaped implants, which are then placed in the surgical wound. Antibiotics are released from the antibiotic-impregnated PMMA by diffusion; tissue fluids surrounding the PMMA implant create a concentration gradient for elution of the antibiotic from the implant into the fluids. Placement of PMMA in a surgically created wound or at the site of infection provides a prolonged high local tissue concentration of the drug during the first few days after insertion, and the concentration decreases with time.130 Although it is variable with the antibiotic used, there is sustained release of antibiotic from the implant. Gentamicin- and amikacin-impregnated PMMA release bactericidal concentrations of the antibiotic for at least 30 days, whereas ceftiofur-impregnated PMMA is unlikely to provide long-term bactericidal concentrations.131 Antibiotic concentrations have been detected more than 2 years after implantation, but elution usually decreases below bacteriostatic level after a few weeks or months. Antibiotics can be added to PMMA used for plate luting in the repair of long-bone fractures or used as implants alongside the repaired fracture in horses.78 This allows high concentrations to be maintained at the site of repair to help prevent infection involving the bone and implants. Because a combination of cefazolin and amikacin provides the best coverage against the most common bacteria isolated from horses with orthopedic infection,10,11 the use of these two antibiotics in PMMA implants allows greater concentrations of antibiotics to be achieved locally at much lower cost than with parenteral administration.

LATER ANTIBIOTIC EFFECTS

Some antibiotics continue to exert a deleterious effect on susceptible bacteria after drug concentrations have decreased below the MIC.132 These postantibiotic effects are believed to occur because of (1) decreased ability of bacteria to grow and reproduce, (2) increased phagocytosis by inflammatory cells as a result of increased opsonization of the bacteria, (3) increased autolytic bacterial enzyme production, and (4) diminished ability of bacteria to adhere to tissues. There is some evidence to suggest that it may in fact be advantageous for the antibiotic concentration to decrease below the MIC for part of the dosing interval to ensure maximal effectiveness. Aminoglycosides, penicillins, cephalosporins, and fluoroquinolones demonstrate an in vitro postantibiotic effect. It is now believed that high peak serum concentrations of aminoglycosides may be more efficacious than prolonged serum concentrations above the MIC.

TOXIC SIDE EFFECTS OF ANTIBIOTICS

Adverse or toxic side effects of antibiotics are not commonly encountered, but when present they can be life threatening (see Table 7-6). Enterocolitis/diarrhea is a relatively common side effect of antibiotic treatment of horses, and it is often associated with *Clostridium difficile* or *Salmonella*.133,134 Antibiotic-associated diarrhea appears to be most common after oral administration, but it may also occur with parenteral administration. Although objective data are not available, anecdotal reports suggest that ampicillin, trimethoprim-sulfonamides, oxytetracycline, and erythromycin are frequently associated with diarrhea. Some of these reports also report diarrhea with ceftiofur when administered IV more frequently than twice daily.

Neuromuscular blockade is a potential side effect of aminoglycoside therapy.135 It is recognized infrequently in horses, but it may be more common when used concurrently with anesthetic agents. Although caution is advised regarding the use of a single daily dose of aminoglycosides preoperatively because of the potential for neuromuscular weakness associated with the use of aminoglycosides when combined with inhalant anesthetics,136 a more recent study has shown that a single high dose of gentamicin does not cause appreciable neuromuscular blockade when administered alone to healthy horses anesthetized with halothane.137 We have used a 6.6-mg/kg dose of gentamicin preoperatively in horses undergoing elective and emergency surgical procedures with no apparent abnormalities. Ototoxicity is also a potential side effect of aminoglycoside therapy.135

Nephrotoxicity is the most common toxic side effect associated with aminoglycoside therapy; it appears to be correlated with a high trough level, which is associated with the accumulation of drug in renal tubules.135,138 Aminoglycosides are resorbed on the brush border of the proximal tubular cells, and this cortical uptake is saturable. Sustained high serum trough concentrations result in greater nephrotoxicosis. Therefore, single high-dose gentamicin administration avoids the likelihood of this complication.

There are reported deleterious effects of fluoroquinolones (enrofloxacin) on bone, tendon, and cartilage in horses;139,140 however, the clinical importance of these effects has not been thoroughly documented. These drugs should be used cautiously in foals. They are not, and should not be, used for routine antibiotic prophylaxis.

Anorexia is not uncommon in horses given metronidazole; approximately 2% of horses administered metronidazole per os develop anorexia.142 Because metronidazole is rarely used prophylactically and because this effect usually develops over time, it is not usually considered a problem in horses undergoing surgery.

EMERGENCE OF BACTERIAL RESISTANCE TO ANTIBIOTICS

The emergence of resistant bacteria has been reported in equine hospitals as it has in human hospitals. The reasons
are probably multifactorial, but most likely they are related to the application, perhaps indiscriminate at times, of antibiotics for prophylactic and therapeutic uses. Because penicillins and aminoglycosides are the most commonly used antibiotics for SSI prophylaxis, the mechanisms for development of resistance to these antibiotics will be briefly discussed.

Methicillin-resistant staphylococci have been isolated from normal healthy horses, horses with SSI or other infections, and horses that were involved in outbreaks on farms and in hospitals.149-147 These findings demonstrate the need for even more stringent guidelines for the appropriate use of antibiotics in horses. These bacteria not only pose a risk for horses but also threaten people working with or around them. It is imperative that clinicians be aware of the risk of antibiotic-resistant bacteria, including MRSA, in their hospital or practice.

Resistance to penicillins or other β-lactam antibiotics such as cephalosporins can result from failure of the antibiotic to penetrate the outer bacterial cell layer and from alteration of penicillin-binding proteins, which decreases the affinity of these proteins for the antibiotic.146 This is the mechanism that occurs in MRSA. Bacteria can also synthesize β-lactamase enzymes, which hydrolyze the cyclic amide bond of the β-lactam ring and inactivate the antibiotic.147 Bacteria synthesize as many as 50 β-lactamase enzymes, depending on the bacterial species.148 Most of these enzymes do not inactivate cephalosporins or anti-staphylococcal penicillins. The gram-negative β-lactamase enzymes are a diverse group that can be encoded by either chromosomes or plasmids.149 E. coli also produces a plasmid-derived lactamase that can inactivate penicillins and cephalosporins.

Aminoglycoside resistance is caused principally by enzymes encoded by genes located on bacterial plasmids, which act internally to alter the aminoglycoside and prevent it from binding to ribosomes.149 Amikacin is the least susceptible of the aminoglycosides to enzymatic inactivation. This plasmid-mediated resistance to aminoglycosides can be transferred between bacteria, so a single type of plasmid may confer cross-resistance to multiple aminoglycosides and to other unrelated antibiotics. Bacteria have developed additional mechanisms to decrease the efficacy of aminoglycosides. For example, some bacteria are less permeable to aminoglycosides, so greater concentrations are required to kill them. Subinhibitory and inhibitory aminoglycoside concentrations lead to resistance in bacterial cells that survive the initial ionic binding.150 This adaptive resistance is caused by decreased aminoglycoside transport into the bacteria.149 Exposure to a single dose of an aminoglycoside is sufficient to cause resistant strains of bacteria with altered metabolism and impaired aminoglycoside uptake. Resistance has been shown to occur within 1 to 2 hours after the first dose of an aminoglycoside.

Bacterial resistance to trimethoprim is typically slow to develop, but it is relatively common in bacteria isolated from horses. Bacterial resistance to sulfonamides occurs via chromosomal mutations or via plasmids. Chromosomal alterations may cause increased bacterial synthesis of PABA, which overcomes competitive substitution of the sulfonamides.150 Cross resistance occurs among sulfonamides.

SUMMARY OF ANTIBIOTIC PROPHYLAXIS

Although antibiotics are an important component of SSI prophylaxis, it is imperative that they be used discriminately. Appropriate principles and guidelines must be followed to decrease the chances of SSI and other complicating infections while minimizing the risk of toxicity, adverse effects, and the emergence of resistant bacterial strains.

CHAPTER 8

Physiologic Response to Trauma: Evaluating the Trauma Patient
Susan J. Holcombe

Traumatic injury in horses is common but usually limited to limb or trunk wounds. Less frequently, horses experience more severe trauma resulting in a substantial systemic response. This acute response to trauma is initiated by pain, blood loss and concomitant hypovolemia, hypoxia, acidosis, and sometimes hypothermia, and it is regulated by neurohumoral, immunologic, and inflammatory mediators. The response to trauma is meant to promote homeostatic mechanisms essential to survival and ultimately healing, but the response can be deleterious, leading to systemic inflammatory response (SIRS) (see Chapter 2), coagulopathy (see Chapter 4), remote organ failure, and death. When the tightly regulated equilibrium of proinflammatory and anti-inflammatory cytokines that controls and coordinates the body’s response to injury becomes unbalanced, it causes either a hyperinflammatory or a severe immunosuppressive state, neither of which is conducive to longevity.1

Classically, the metabolic response to trauma has been described by two phases: ebb (shock phase) and flow (catabolic, followed by an anabolic phase).2,3 The ebb or shock phase occurs during the first several hours after injury and is characterized by the compensatory physiologic responses to shock (see Chapter 1), as well as by acute inflammation. Next, the patient enters the flow phase, which is initiated by a catabolic state meant to promote tissue healing.4 This second phase is an intense metabolic state, characterized by a hyperdynamic stress response, fluid retention and edema, and hypermetabolism, which is propagated by cytokines, reactive oxygen metabolites, nitric oxide, and arachidonic acid derivatives.5 This phase may last for days to weeks. Once volume deficits have been eliminated, wounds have closed, and infection has been controlled, the anabolic stage begins, and this represents the end of the flow phase.5 It is characterized by a return to normal hemodynamics, diuresis, the reaccumulation of protein and body fat, restoration of body function, and weight gain.2 This chapter summarizes the acute systemic traumatic responses and then briefly reviews the diagnostic steps for evaluation of thoracic, abdominal, and cranial trauma.

EBB—THE SHOCK PHASE

Components of severe trauma include pain, tissue injury, hypovolemic shock, and, at times, hypothermia. Each of these events contributes to the stress response that results from trauma and is a potent initiator of the sympatho-adrenal axis and secretion of catecholamines and cortisol.2 Blood loss and resulting hypovolemia cause subsequent release of catecholamines and antidiuretic hormone and activation of the renin-angiotensin-aldosterone system in an attempt to restore vascular volume.6 Epinephrine and norepinephrine cause vasoconstriction and increase heart rate and stroke volume to restore perfusion and oxygen delivery to the tissues. Adrenal secretion of cortisol is mediated by the hypothalamic-pituitary-adrenal axis. Stimuli for cortisol release trigger neural afferent signals that stimulate corticotrophin-releasing factor from the hypothalamus, signaling secretion of adrenocorticotropic hormone (ACTH) from the anterior lobe of the pituitary gland.7 The target organ for ACTH is the adrenal cortex, which stimulates synthesis and release of cortisol. The amount of cortisol released is relative to the degree of injury. Glucocorticoids cause sodium retention, stimulate insulin resistance, and help to fuel a high-energy state by stimulating gluconeogenesis, lipolysis, and protein catabolism.8 Increased circulating levels of cortisol also enhance the catabolic effects of tumor necrosis factor (TNF) and interleukin (IL)-1 and IL-6, inflammatory cytokines found in high circulating levels in trauma patients.7,8

Pain

Pain results from the initial traumatic injury and may persist throughout the healing process. Pain produces a strong sympathetic response and contributes to the stimulus for cortisol secretion. The fact that pain is not experienced during anesthesia may be an important reason that extensive trauma of major surgery is often well tolerated, whereas similar amounts of tissue injury, incurred during accidental trauma, cause more severe metabolic responses.2,9,10 Such evidence strongly suggests that preemptive and continued analgesic therapy is essential in patients with traumatic injury to minimize the stress response and improve immunologic function and tissue healing11–16 (Table 8-1). The importance of neural afferents from the site of tissue injury is confirmed in paraplegic humans, in whom the usual perioperative rise in cortisol levels is not seen if the operation is performed below the level of spinal cord damage.12,17 Pain, as well as other events that stimulate a sympathetic response, enhance endorphin release from the adrenal glands, which functions in part to decrease the sensation of pain. Endogenous opioids also act as regulators of the stress response by modulating the release of catecholamines from the adrenal medulla, exerting inhibitory feedback on pituitary activation and decreasing ACTH release.

Tissue Injury

The response to tissue injury is an essential component of the acute response to trauma. Localized inflammation and coagulation may lead to systemic inflammatory and deranged coagulation events. Endothelial disruption at sites of injury and tissue ischemia initiate the release of inflammatory mediators and coagulation factors. Exposure of the subendothelial collagen and basement membrane activates circulating Hageman factor (factor XII), which initiates the intrinsic coagulation pathway, and the complement cascade,

which also incites an inflammatory response. Impaired coagulation may be caused by hypothermia as well as by aggressive fluid resuscitation, resulting in dilutional coagulopathy. Another important set of processes activated by injury, ischemia, and endothelial disruption is stimulation of arachidonic acid metabolism, releasing prostaglandins and leukotrienes, which are potent mediators of vascular tone and cause inflammation, cellular activation and cytokine production, and coagulation. The role of cytokines in the pathophysiologic alteration of trauma is not completely understood. There is strong evidence, however, suggesting that one of the important initiating events in posttraumatic inflammation is the overproduction of the proinflammatory cytokines TNF-α, IL-1, and IL-6.

Edema
A vital component of the initial responses to trauma is the restoration of tissue perfusion and maintenance of body fluids. This occurs by a combination of vascular constriction and fluid preservation. Vasoconstriction occurs in an attempt to stop blood loss from the wound and to preferentially perfuse vital organs. Catecholamines, cortisol, aldosterone, and angiotensin II promote sodium and water retention mechanisms and increased sympathetic tone, which cause capillary physiology is altered, leading to salt and water loss from the vascular space into the interstitium. This occurs because of the presence of circulating and local vasoactive mediators and increased sympathetic tone, which cause postcapillary vasoconstriction and subsequent increase in intraluminal capillary pressure.

Hypoproteinemia from blood loss and crystalloid resuscitation decreases intravascular oncotic pressure. Increased capillary interstitial pressure and decreased oncotic pressure, in addition to inflammation, which may increase the “leakiness” of capillaries, lead to the egress of salt and water from the capillaries, producing systemic edema formation distant from the original site of injury. The magnitude of edema formation tends to be proportional to the severity of the injury and is progressive as long as the stress state persists. Edema impairs wound healing at the site of injury but also contributes to impaired microcirculatory blood flow, decreased oxygen delivery, and consumption by the tissues, systemically.

Hypothermia
Hypothermia, defined as a core body temperature below 35°C (95°F), may develop in trauma patients as a response to cold exposure, especially if the horse is wet, or as a response to failure of normal physiologic homeothermic mechanisms, which can be a complication of shock. Clinical hypothermia is uncommon in adult horses but common in foals with severe trauma because they have a higher body surface area–to–body mass ratio. Hypothermia may lead to coagulopathies, cardiac arrhythmia, and impaired immune function.

Homeothermia describes the maintenance of constant internal temperature despite changing environmental temperature. This is accomplished by matching metabolic thermogenesis and heat loss. Heat loss occurs by four mechanisms: convection, conduction, radiation, and evaporation. Convective heat loss occurs when heat is transferred to the air in contact with the body. It is dependent on air velocity. Therefore, it is important to move injured horses into an enclosed area for evaluation and treatment. Conductive heat loss occurs by transfer of heat to an object directly contacting the body. Placing foals on heated water blankets versus cold stainless steel tables minimizes conductive heat loss. Radiation is defined as heat loss to the environment based on a gradient of temperature and is minimized by placing blankets on the patient and maintaining a warm ambient temperature. Evaporation occurs by conversion of water to the gaseous phase, making it important to keep injured patients dry.

The hypothalamus regulates body temperature and responds to thermoreceptors located along the internal carotid artery, the reticular area of the midbrain, and the preoptic and posterior hypothalamus as well as peripheral receptors in the skin. The normal response to cold includes increased muscular activity or shivering and increased thermogenesis. Increased levels of epinephrine and norepinephrine with a subsequent rise in metabolic rate cause
increased metabolic thermogenesis. These processes may be impaired in trauma patients. Three basic mechanisms contribute to hypothermia:

1. Traumatic injury can alter normal central thermoregulation at the hypothalamus and block the shivering response.
2. If the trauma patient experiences hypovolemic shock, thermogenesis decreases because of impaired oxygen delivery to the tissues.
3. Although it is an infrequent cause, infusion of large volumes of cold fluids may contribute to hypothermia.

Hypothermia is a concern because it can lead to coagulopathies that result from impaired platelet function and altered enzymatic kinetics in the coagulation cascade. Severe hypothermia has been shown to impair cardiovascular status by decreasing cardiac output, and by causing hypotension and fatal arrhythmias. Finally, hypothermia causes the oxyhemoglobin dissociation curve to shift to the left, increasing the affinity of hemoglobin for oxygen.

FLOW—THE CATABOLIC PHASE
After trauma, energy demands increase dramatically because basal metabolic rate can more than double in these patients. This hypermetabolic state is directly related to a prolonged stress response, which supports a hyperdynamic circulatory state and increased oxygen consumption as well as generalized inflammation. Cytokines, specifically TNF, formerly known as cachectin, are important mediators of the posttraumatic hypermetabolic state. In research animals, the complete manifestation of the stress response is seen when cortisol, glucagons, and epinephrine were infused into the patient in the presence of inflammation, suggesting that the hypermetabolic response is mediated by a combination of central stress responses and tissue inflammation.

This hypermetabolic state must be fueled. After severe trauma, total-body catabolism is increased, particularly within skeletal muscles. Amino acids are used for energy production via gluconeogenesis, and glycogen is converted to glucose, leaving patients glycogen depleted and in a negative nitrogen balance. Protein breakdown results in a significant loss of muscle mass and may progress to the loss of visceral protein mass as well. The mediators of altered protein metabolism include cortisol and glucagon as well as elevated levels of catecholamines and cytokines, particularly TNF, IL-1, and IL-6, which can impair wound healing. Nutritional support is vital in trauma patients because of increased energy demands, but protein breakdown and glycogen synthesis will continue through the catabolic phase until anabolism begins.

Insulin levels are initially low after injury but subsequently rise to normal or elevated levels. Hyperglycemia may occur as a result of peripheral insulin resistance caused by persistent elevations of glucagon, cortisol, and epinephrine. Two of the major functions of insulin are inhibition of the rate of hepatic glucose production and stimulation of glucose uptake in peripheral tissues. Therefore, the insulin resistance in the stress state may be central to persistent hyperglycemia as well as to breakdown of muscle, fat, and glycogen. After injury, fat is oxidized at an accelerated rate; this effect is mediated by sympathetic stimulation; increases in epinephrine, glucagon, and cortisol; and insulin resistance. Fatty acids are released into the circulation and become available as an energy substrate. However, fat mobilization can be limited by lactate and hyperglycemia.

FLOW—THE ANABOLIC PHASE
The anabolic phase of recovery may last for days to weeks. During this time, the systemic neurohumoral system returns to normal, edema dissipates, and catecholamine and cortisol levels stabilize, as do the systemic parameters of the patient. Visceral and muscle protein is synthesized and organ function improves. Appetite returns and weight gain begins.

There has been increasing interest in the development of effective agents that can be safely used to promote anabolism in recovering trauma patients and others susceptible to chronic cachexia. An anabolic androgenic steroid, oxandrolone, has been effective in treating catabolic disorders in human patients. Administration of oxandrolone has been associated with improvements in body composition and in muscle strength and function. Improved status of underlying disease, improved recovery from acute catabolic injury, and improved nutritional status are significantly better than placebo in the vast majority of oxandrolone trials.

EVALUATING THE TRAUMA PATIENT
Classes of traumatic injury include blunt and penetrating trauma. Blunt trauma is a distributed dissipation of kinetic energy by concussion or by deceleration. Blunt trauma can lead to direct contusive injury, shearing, vascular disruption, and indirect lacerations secondary to skeletal fracture. A horse suffers blunt trauma during a transportation accident, when a trailer is hit or capsizes, if a moving vehicle hits the horse, or if the horse falls. In these instances, it is imperative to examine each body system, because injuries from blunt trauma may not be obvious and may result in thoracic or abdominal bleeding, diaphragmatic hernia, or cranial injury. Unlike blunt trauma, penetrating trauma is a more focal dissipation of a projectile’s kinetic energy, and it leads to direct-impact lacerations and fractures. Examples of penetrating trauma in horses include gunshot injuries and impalement on fenceposts. Although thorough examination of the horse is exigent, injury from penetrating trauma is more obvious as long as an entry wound is found. Blunt or penetrating trauma can result in respiratory, cardiovascular, neurologic, gastrointestinal, or musculoskeletal system injury, and therefore each body system must be assessed during evaluation of the patient.

Thoracic Trauma
Thoracic trauma may result from blunt or penetrating injury. Broadly categorized disorders of thoracic trauma include pneumothorax, hemothorax, thoracic wounds, and fractured ribs. Pulmonary contusions and rib fractures frequently occur with blunt trauma, whereas cardiac tamponade and pneumothorax are more common after penetrating trauma. Injuries that cause blunt trauma may ultimately result in...
Physiologic Response to Trauma

Penetrating trauma, because fractured ribs may lacerate pulmonary parenchyma or perforate the heart or cardiac vessels. Blunt thoracic trauma is more common in neonatal foals and may be caused by compression in the pelvic cavity during parturition. In the evaluation and treatment of thoracic wall injury, the principal concerns are cardiovascular embarrassment, pain management, and pulmonary compromise. On an emergency basis, respiratory insufficiency is one of the most serious physiologic consequences of thoracic trauma, and early respiratory support for the injured horse is concerned primarily with restoration and maintenance of adequate ventilation and oxygenation.

The basic principles of treatment of thoracic injury include rapid restoration of the airway, supplemental oxygen, decompression of pneumothorax, and covering open thoracic wounds. Subjectively, horses with thoracic injury may seem anxious because of respiratory distress, or in pain as a result of wounds or fractures. Signs of respiratory distress include excessive respiratory efforts, tachypnea, nostril flaring, audible inspiratory and expiratory sounds, accentuated thoracic and abdominal excursions, and cyanotic mucous membranes. The respiratory rate, pattern, and depth of breathing are evaluated because alterations in the respiratory pattern may be suggestive of specific lesions. For example, a horse with fractured ribs may breathe with a shallow respiratory pattern and decreased tidal volume as a result of thoracic splinting that is caused by pain. Horses with pneumothorax or hemothorax may have a rapid, shallow respiratory pattern, as well. Auscultation of the entire lung fields identifies pneumothorax or hemothorax. With pneumothorax, lung sounds are absent dorsally. With hemothorax, lung sounds are absent or diminished ventrally, but the heart sounds resonate over a large area of the ventral thorax.

Arterial blood gas measurements provide important information on the horse's ability to ventilate and maintain normoxia. Serial samples help determine if the horse is deteriorating or responding favorably to therapy. Palpation of the thoracic cage for swelling, subcutaneous emphysema, and crepitus will help identify injuries such as rib fractures and chest wounds. Thoracic radiographs allow detection of rib fractures, pneumothorax, hemothorax, and thoracic foreign bodies. Thoracic ultrasonography may establish the diagnosis of pneumothorax or the degree of hemothorax present, and it provides guidance for pleurocentesis or placing chest tubes, which are indicated if fluid or air needs to be removed from the pleural space. Thoracoscopy may be performed in the standing and hemodynamically stable horse to assess structures within the chest after thoracic trauma. Indications for exploratory thoracoscopy include ongoing hemorrhage, retained hemothorax, suspected diaphragmatic injuries, suspected cardiac injury, intrathoracic foreign body or contamination, and persistent bronchopleural fistula. Exploration of each hemithorax can be performed, if warranted, from the caudal dorsal quadrant and continuing cranially. The collapsed lung, diaphragm, aorta, and esophagus can be assessed. On the right side, the azygous vein, thoracic duct, and pulmonary veins may be viewed.

Cardiovascular assessment of horses with thoracic trauma is important because of the risk of damage to the heart, great vessels, and intercostal and pulmonary parenchymal vascular lature. Tachycardia, palpably weak peripheral pulses, and pale mucous membranes may indicate severe, ongoing hemorrhage. Serial arterial blood gases, packed cell volume, and total protein will help assess blood loss and hypoxemia. (For additional details on diagnosis and treatment of thoracic trauma, see Chapter 47).

**Pneumothorax**

Ventilatory embarrassment associated with pneumothorax is believed to be the result of equilibration of atmospheric and intrathoracic pressures through a defect in the chest wall or lung. This allows atmospheric air to enter the pleural space, which causes the intrapleural pressure to rise toward atmospheric pressure and produces pneumothorax and collapse of the lung. Bilateral pneumothorax may develop in horses because they have an incomplete mediastinum. Pneumothorax can be categorized as open, closed, or tension pneumothorax. Open pneumothorax results from penetrating, open chest wounds, through which air is drawn into the pleural space during inspiration. Closed pneumothorax is caused by air entering the pleural space from the lung, resulting from a ruptured bulla or closed rib fracture where the rib fragment has lacerated the lung parenchyma.

Tension pneumothorax is present when intrapleural pressure exceeds the atmospheric pressure throughout expiration and often during inspiration as well. Tension pneumothorax usually occurs because of a pleurocutaneous fistula, such as a sucking chest wound, that acts like a one-way valve. During inspiration, when the pleural pressure is negative, air moves into the pleural space while the opening is patent. During expiration, the communication is partially or totally occluded by a flap or valve-like opening, and air accumulates in the pleural space under positive pressure. The development of tension pneumothorax is exceptionally dangerous because of the severe deterioration in the cardiopulmonary status of the horse. This deterioration is the result of severe hypoxemia, and the partial pressure of arterial oxygen (PaO2) may fall to 22 to 28 mm Hg.
Diminished venous return to the heart has been implicated as the cause of cardiopulmonary collapse; however, when hypertension pneumothorax was created experimentally in monkeys and goats, cardiac output was unchanged. The genesis of the distress was related to precipitous decreases in PaO₂, which fell from 90 to 22 mm Hg.³⁷

Pneumothorax may be treated after the wounds have been sealed by carefully inserting a large-gauge needle, teat cannula, or thoracostomy tube into the dorsal thoracic cavity just in front of the 12th to 15th rib, avoiding the vessels running on the caudal surfaces of the ribs. The air may be evacuated with a 60-mL syringe and a three-way stopcock or suction apparatus. Reexpansion pulmonary edema is a complication of rapidly reinflating a lung after a period of collapse secondary to pneumothorax, hemothorax, or pleural effusion. Horses with reexpansion pulmonary edema may develop varying degrees of hypoxemia and hypotension. Reexpansion pulmonary edema is likely caused by increased permeability of the pulmonary vasculature.³⁸ The edema fluid has a high protein content, suggesting that it is leakage of the capillaries rather than an increased hydrostatic pressure that is responsible for the formation of the edema.³⁸ Capillary damage may be caused by mechanical trauma associated with lung reexpansion or reperfusion injury.³⁸ To minimize the risks of reexpansion pulmonary edema, a pressure of −20 cm H₂O or less should be used, and the air should be removed from the thorax slowly.³⁸ Evacuation may need to be repeated or continuous because of continuing air leaks from the wound.

**Hemothorax**

Generally, a horse with a massive hemothorax caused by a penetrating wound to the heart succumbs soon after the injury. However, if hemothorax is suspected, restoring circulating blood volume prior to draining the chest cavity is suggested. Evacuating the hemothorax from the pleural cavity will aid in ventilation because the fluid displaces the functional lung, compromising alveolar ventilation. Removing the hemothorax also decreases the risk of developing septic pleural effusion and pleural adhesions. Thoracentesis is an emergency procedure for hemothorax in which alveolar ventilation is impaired because of decreased lung expansion. Radiography or ultrasonographic examination is used to determine the level and amount of fluid to be removed. A 7-cm area is clipped and surgically prepared, ventrally, at the seventh intercostal space. The skin, subcutaneous tissue, cranial aspect of the rib, and parietal pleura are infiltrated with local anesthetic. A stab incision is made through the skin over the cranial aspect of the rib and then a teat cannula, a catheter, or a chest tube is advanced through the skin incision, intercostal muscles, and parietal pleural lining until a distinct popping sensation is felt. The catheter can be redirected if neither fluid nor air is aspirated. The caudal aspect of the rib’s intercostal vessels and nerves and sites more cranial than the seventh intercostal space should be avoided. In cases of hemothorax, a large-bore catheter or chest tube with a trocar may be used to rapidly drain large volumes or thickened fluid with blood clots. A one-way valve, such as a Heimlich valve, can be attached to the tube for continuous one-way flow (see Chapter 18).

Because of the proximity of the abdomen to the thorax, evaluating the horse for signs of acute abdominal crisis is important, especially if penetrating trauma to the thorax invaded the abdomen. Because the dome of the diaphragm extends to the sixth rib on expiration, horses with wounds caudal to this or with deep penetration warrant peritoneal paracentesis to detect potential visceral damage or rupture.⁴⁰

**Abdominal Trauma**

Abdominal injury can occur with blunt or penetrating trauma and result in hemorrhage, contamination, gastrointestinal viscus rupture, or eventration. Thorough physical examination is indicated because these patients may be cardiovascularly unstable with injuries to other body systems. Penetrating wounds that enter the abdomen causing peritonitis require immediate attention. The exposed intestine should be thoroughly lavaged with sterile balanced polyionic solution and replaced within the abdomen. The abdominal wall defect should be closed, if possible, and a large bandage applied to the abdomen to support the wound and keep the abdomen closed. Broad-spectrum antimicrobials and nonsteroidal anti-inflammatory medication should be instituted prior to referral to a surgical facility. Abdominal exploratory surgery is frequently warranted after eventration to assess bowel viability, resect damaged intestine, lavage the abdomen, and properly close the abdominal wound. Penetrating abdominal injury, such as a gunshot wound or an impalement on a fencepost, may cause parenchymal damage to the spleen, liver, or kidneys, resulting in hemorrhage, major vessel injury, or gastrointestinal viscus damage, including serosal tears, mural hematomas, mesenteric avulsion, and intestinal perforation.⁴⁶

Diagnostic techniques used to assess the abdomen after trauma include peritoneal paracentesis, rectal palpation, abdominal ultrasonography, abdominal radiographs, and laparoscopy. The diagnosis of hemoa or peritoneal fluid evaluation and abdominal ultrasonography. Ultrasonic examination shows free abdominal fluid with a swirling pattern (Fig. 8-2). The presence of blood in the abdomen is confirmed with peritoneal paracentesis and assessment of the packed cell volume and total solids of the fluid. Gastrointestinal viscus rupture can also be diagnosed with abdominal ultrasound and peritoneal paracentesis. Free abdominal fluid is detected ultrasonographically and the presence of gastrointestinal contents confirmed with peritoneal fluid evaluation. The fluid is frequently serosanguineous, with a foul odor, and grossly contaminated with feed. Cytologically, multiple populations of bacteria and degenerative neutrophils confirms the diagnosis. If gastrointestinal rupture is suspected but the peritoneal fluid does not appear grossly contaminated, measurements of pH, glucose, and lactate may be helpful, in addition to cytology. Horses with septic peritonitis have significantly lower peritoneal fluid pH and glucose concentrations than horses with nonseptic peritonitis and healthy horses. Serum-to-peritoneal fluid glucose concentration differences greater than 50 mg/dL, peritoneal fluid glucose concentration less than 30 mg/dL, peritoneal fluid pH less than 7.3, and fibrinogen concentration greater than 200 mg/dL are also highly indicative of septic peritonitis.⁴⁷ Exploratory laparoscopy can be performed in the standing horse after abdominal
Splenic hematoma, mesenteric avulsion, diaphragmatic hernia, and viscus rupture with gross peritoneal contamination have been diagnosed. Thoracic radiographs are indicated if diaphragmatic hernia is suspected (Fig. 8-3).

Cranial Trauma

Cranial injuries vary in severity and range from subtle alterations in mentation to unresponsive coma. Physical examination and neurologic evaluation should be performed, and a modified Glasgow Coma Scale can be used to assess mentation (Table 8-2). In human patients, a score of 13 to 15 indicates mild brain injury, 9 to 12 moderate injury, and 3 to 8 severe brain injury. The score is established by adding the horse’s best responses in the three categories listed in Table 8-2.

Any portion of the calvaria can be fractured, although certain injuries are more common. Most cranial injuries occur because the horse falls over backwards, striking the poll, or because the horse runs into something or is kicked, injuring the frontal bones. Severe brain injury may occur with or without skull fractures because the brain recoils within the cranial vault, resulting in contusion, vascular injury, and axonal disruption. When horses fall over backwards, striking the poll, portions of the nuchal crest, parmastoid processes, and occipital condyles can fracture.

More serious injuries result from the actions of the rectus capitis ventralis muscles on the basisphenoid and basioccipital bones. These muscles originate on the ventral surface of the cervical vertebrae and insert on the ventral aspect of the basioccipital bones. Contraction of these muscles flexes the head, but when the head falls and the head is extended, the action of these muscles can result in avulsion fractures of the junction of the basisphenoid and basioccipital bones (more common in young horses) (Fig. 8-4), or in complete avulsion of a portion of the basilar bones (Fig. 8-5). These injuries may lead to fatal hemorrhage if the occipital arteries or their branches are lacerated. Hemorrhage into the cervical tissue planes and between the guttural pouches may occur (Fig. 8-6).

Fracture of the basilar bones can cause injury to cranial nerves V, IX, and X, exhibited by loose jaw tone, decreased facial sensation, dyspnea, and dysphagia. Injury to the petrous temporal bone area may cause vestibular signs and facial nerve paresis because of injury to cranial nerves VII and VIII. Therefore, horses with poll trauma may have evidence of vestibular syndrome and exhibit a head tilt, leaning, or circling toward the side of the lesion. The vestibular signs worsen if the horse is blindfolded. Also, horizontal or rotary nystagmus may be detected. These horses may have a hypometric or spastic gait because of cerebellar injury. If the optic nerves have been stretched or torn, these horses will be blind with absent papillary light response and dilated pupils. Examination of the size, symmetry, and response to light of the pupils is critical. A change in pupil size from bilaterally constricted to bilaterally dilated, with lack of response to light, is indicative of progressive brain injury. Asymmetric or bilaterally miotic pupils indicate serious injury, and the prognosis for recovery is poor.
Horses with frontal or parietal bone trauma frequently have epistaxis from sinus or ethmoid injury. These horses may be depressed, unresponsive, or demented, or they may exhibit compulsive walking or head pressing. If the occipital cortex is injured, vision and the menace response are impaired in the eye contralateral to the lesion. The pupillary light response should be intact.46

Diagnostic modalities for cranial trauma include plain radiographs, computed tomography (CT), CT with contrast enhancement, endoscopy, cerebral spinal fluid evaluation, and magnetic resonance imaging.49 Because of the complex nature of the anatomy of the equine head, superimposition of numerous structures, and poor soft tissue differentiation, radiography may be of limited value in the diagnosis of basilar skull fractures. However, in many horses, radiographic changes such as soft tissue opacification of the guttural pouch region, irregular bone margination at the sphenoparietal line, attenuation of the nasopharynx, ventral displacement of the dorsal pharyngeal wall, and the presence of irregularly shaped bone fragments in the region of the guttural pouches are suggestive of a fracture of the skull base.50 CT with or without contrast enhancement is a sensitive diagnostic modality for detecting skull fractures or brain trauma such as focal parenchymal hemorrhage or subdural hemorrhage.51

Emergency therapy for horses with head trauma and brain injury includes establishing an airway if needed and oxygen insufflation if the horse is hypoxemic (15 L/min), anti-inflammatory and analgesic medications. Hypertonic saline (7.5%; 4 mL/kg) has been demonstrated to exert neuroprotective properties after traumatic brain injury by osmotic mobilization of parenchymal water and improvement of microcirculation, as well as its having anti-inflammatory properties. When administered with dextran, hypertonic saline resulted in lower intracranial pressure, improved neurologic recovery, and less morphologic damage after subarachnoid hemorrhage in rats.52,53 Posttrauma administration of magnesium sulfate (100 mg/kg) has been shown to decrease cerebral edema, attenuate defects in the blood-brain barrier, and attenuate long-term motor and cognitive deficits after traumatic brain injury.54-56 In addition, administration of magnesium sulfate supports endogenous antioxidant function within the brain after injury.54-56

Horses with frontal or parietal bone trauma frequently have epistaxis from sinus or ethmoid injury. These horses may be depressed, unresponsive, or demented, or they may exhibit compulsive walking or head pressing. If the occipital cortex is injured, vision and the menace response are impaired in the eye contralateral to the lesion. The pupillary light response should be intact.46

Figure 8-4. Lateral skull radiograph of a 3-month-old foal that flipped over backward, landing on its poll. Notice the bony fragment and step at the junction of the basisphenoid and basioccipital bones (arrow). C1, first cervical vertebrae; C2, second cervical vertebrae; GP, guttural pouch.

Figure 8-5. Lateral skull radiograph of a 14-year-old horse that flipped over backward and fell. Note the bone fragment (white arrow), which at postmortem examination was determined to be the basisphenoid bone completely avulsed from its normal position at the base of the skull (black arrow).

CHAPTER 9

IMPLANT CHARACTERISTICS
Biomaterials of either natural, processed natural, or synthetic origin are used as implants and devices to direct, supplement, and replace or restore tissue function. Metals, polymers, ceramics, and composites of these three are the primary substances used today in manufacturing biomaterials. Design, material selection, and biocompatibility are the critical issues surrounding the manufacture of medical implants and devices. Ideally, materials should be inert, strong enough to allow biomechanical loading, easily handled, noncorrosive, nonallergenic, nontoxic, noncarcinogenic, easily sterilized, inexpensive, and resistant to infection. The ideal biomaterial does not exist; however, the discovery of new materials, alterations in biomaterial composites, and combining metals, ceramics, and polymers have improved product structure, quality, and biocompatibility. Just a few examples of biomaterial applications are intravenous, urinary, and gastric catheters; heart valves and vascular grafts; orthopedic devices such as joint replacement components, pins, screws, plates, rods, tacks, suture anchors, and fixators; dental and ophthalmic implants; tissue adhesives; wound dressings; and suture materials. Initially, readily available substances or materials were used, but today biomaterial science is very sophisticated, with endless possibilities in medical application and construct design.

BIOCOMPATIBILITY
Biocompatibility is a descriptive term pertaining to the ability of a material to elicit an appropriate and predictable host response. The definition extends beyond the chemical composition of the implant to include surface and structural compatibility. Surface compatibility is the chemical, biologic, and physical suitability of the implant surface to interact with host tissues. Structural compatibility is the optimal adaptation to the mechanical behavior of the implant in host tissues. Biocompatibility now emphasizes two areas, biosafety and biofunctionality. Biosafety evaluates the deleterious effects of biomaterial on the host. Biofunctionality deals with the ability of the material to perform with an appropriate host response to a specific application. With pressure to reduce animal testing models, new techniques have evolved, and these trends in biocompatibility testing were recently reviewed. Simple and sophisticated in vitro systems have evolved using human cell line cultures designed to evaluate specific applications of medical devices. These techniques have become the industry standard, because biocompatibility reactions occur at the cellular level and many independent events may occur with interacting stimuli contributing to the overall response.

Host Interactions
When biomaterials interact with a biologic system, the host exhibits a variety of complex reactions. Responses differ depending on whether the material is toxic, inert, resorptive, or bioactive. If the material is toxic, the surrounding tissue dies. Inert materials exhibit minimal chemical reactions with exposed tissue, yet fibrous tissue of varying thicknesses forms at the implant–tissue interface. When biomaterials are almost inert and the interface is not chemically or biologically bonded, there is relative movement, and a nonadherent fibrous capsule is formed progressively in both hard and soft tissues. Biodegradable materials are slowly dissolved by the surrounding tissue or they are used as drug-delivery systems. Bioactive materials are nontoxic and biologically active, and they form an interfascial bond with surrounding tissues through time-dependent, kinetic modification of their surfaces.

Future biomaterials will be used to incorporate biologic factors. They will recruit cell lines and minimize inflammation and infection while improving bioactivity and compatibility with surrounding tissues. Materials will be designed to provide improved mechanical integrity and

BIOCOMPATIBILITY
Biocompatibility is a descriptive term pertaining to the ability of a material to elicit an appropriate and predictable host response. The definition extends beyond the chemical composition of the implant to include surface and structural compatibility. Surface compatibility is the chemical, biologic, and physical suitability of the implant surface to interact with host tissues. Structural compatibility is the optimal adaptation to the mechanical behavior of the implant in host tissues. Biocompatibility now emphasizes two areas, biosafety and biofunctionality. Biosafety evaluates the deleterious effects of biomaterial on the host. Biofunctionality deals with the ability of the material to perform with an appropriate host response to a specific application. With pressure to reduce animal testing models, new techniques have evolved, and these trends in biocompatibility testing were recently reviewed. Simple and sophisticated in vitro systems have evolved using human cell line cultures designed to evaluate specific applications of medical devices. These techniques have become the industry standard, because biocompatibility reactions occur at the cellular level and many independent events may occur with interacting stimuli contributing to the overall response.

Host Interactions
When biomaterials interact with a biologic system, the host exhibits a variety of complex reactions. Responses differ depending on whether the material is toxic, inert, resorptive, or bioactive. If the material is toxic, the surrounding tissue dies. Inert materials exhibit minimal chemical reactions with exposed tissue, yet fibrous tissue of varying thicknesses forms at the implant–tissue interface. When biomaterials are almost inert and the interface is not chemically or biologically bonded, there is relative movement, and a nonadherent fibrous capsule is formed progressively in both hard and soft tissues. Biosorbable materials are slowly dissolved by the surrounding tissue or they are used as drug delivery systems. Bioactive materials are nontoxic and biologically active, and they form an interfascial bond with surrounding tissues through time-dependent, kinetic modification of their surfaces.

Future biomaterials will be used to incorporate biologic factors. They will recruit cell lines and minimize inflammation and infection while improving bioactivity and compatibility with surrounding tissues. Materials will be designed to provide improved mechanical integrity and
corrosion resistance while maintaining improved biocompatibility.

**Biomaterial Testing**

Testing presently encompasses a number of classical test methods for structural and biologic evaluation of medical devices, under the guidance of the International Standardization Organization (ISO). The ISO presents guidelines for suitable tests and defines important principles of these tests. These include positive and negative controls, extraction conditions, choice of cell lines and cell media, and other important aspects of test procedures. Biocompatibility testing includes in vitro and in vivo evaluations.

**Cytotoxicity Testing**

Cytotoxicity leads the area of importance in the evaluation process. Cell morphology studies measure cell growth, metabolism, and damage from exposure to new materials. Metabolic studies evaluate impairment to the mitochondrial enzyme succinate dehydrogenase. Exposure of cell cultures to new materials is used to evaluate the effects of DNA synthesis on cell proliferation. Membrane integrity tests evaluate structural and functional membrane changes on exposure to new materials. Blood or hemocompatibility studies measure interactions related to immediate, prolonged, or repeated exposure to the device. These studies evaluate platelet, red blood cell, polymorphonuclear cell, and macrophage function. Clotting time measurements are assessed.

**Cell Adhesion Testing**

Cell adhesion testing ranks second in importance to cytotoxicity testing of biomaterials. Thrombogenicity is a reflection of plasma protein fibrinogen adherence, platelet adhesion and activation, suppression of protein adsorption, and blood cell adhesion resistance. Products are also evaluated for bacterial adhesion properties. The effects of alkaline and acid fluid media on materials are evaluated. Materials are exposed to physiologic fluids including plasma and serum, as well as to organic chemicals. Electron microscopy evaluates cell spreading in those materials designed for integration into host tissues. Cell proliferation studies are critical in fracture repair devices, especially those that are biodegradable, as they will be replaced by host tissues. Tissue sections are immunohistochemically stained to identify cell types present near the implant.

Mechanical testing has become more refined and includes the study of wear products that are released from devices over time. Materials undergo mechanical testing for stress, strain, compression, and cyclic bending. Spectroscopy is used to evaluate the product’s elemental surface composition, its absorption behavior, and its structural surface properties before and after mechanical testing. X-ray diffraction measurements evaluate structural information, viscoelasticity, and tensile (stress/strain) properties. Viscosity, thermal properties, and contact angle are evaluated.

Mutagenesis is evaluated by the detection of mutations, seen as changes in metabolic function in bacteria exposed to new materials, as well as by animal model studies.

Carcinogenesis is a critical issue for implants designed for long-term function. These studies are carried out in animal models.

As genetic information emerges and new cytokines and growth factors are discovered, an understanding and insight into fundamental cellular mechanisms and specific actions on biologic structure will continue to unfold. Molecular regulators, signaling receptors, and binding sites will be determined and understood, allowing investigators to use bioactive molecules to turn activities on and off, altering cellular function within microenvironments. For example, transgenic mice developed for the study of specific abnormalities are used to test interactions with biomaterials in bone, muscle, tendon, and connective tissue.

**Biomaterial Interactions**

All materials elicit a host response, but the degree varies greatly between biomaterials. This can be attributed to the biomaterial’s properties. Presently, no material implanted in living tissues is totally inert. Metals are selected for their high strength, ductility, and resistance to wear. Disadvantages encountered with metals include corrosion, excess stiffness compared with the surrounding tissue, high density, and release of metal ions that may incite allergic tissue reactions.

**Corrosion**

Corrosion occurs by ionization, oxidation, or hydroxylation. Electrochemical and pH changes are factors in this process. Physical processes also cause corrosion. Crevice corrosion is the most common; it results from improper component fit or develops in the presence of a defect in the metal surface. Scratches or defects caused by improper handling cause pitting corrosion. Galvanic corrosion occurs when dissimilar metals are in direct contact and are exposed to a conductive medium. Stress corrosion occurs when a metal is subjected to opposing mechanical forces, creating an electrochemical potential leading to corrosion. Fretting corrosion occurs when metal is physically removed as a result of motion between two components. The effect of relative movement plays a role, even with quasi-inert implants.

**Movement**

Movement eventually leads to deterioration in function of an implant, or of the tissue at the implant–tissue interface. Development of a thick fibrous capsule can rapidly lead to implant loosening and subsequent failure. Small implant particles are phagocytosed and removed from the area. With the death of the cell, particles are deposited in lymphatic tissue, where they can migrate and incite a foreign body reaction. Metal ion release may stimulate neutrophils to release lysosomal enzymes that may result in implant loosening, patient discomfort, and allergic reactions. Some metal plates provide high axial dynamic compression. However, the stiffness of the implant is complicated by bone atrophy below the plate, secondary to stress shielding, which ultimately weakens the bone. Wear particles that are released from metals, ceramics, and polymers can incite inflammatory conditions that vary in severity.
Surgical Biology

**IMPLANT FORMS AND MATERIALS**

Available implants and implant forms are listed in Table 9-1. Solid implants are constructed primarily of ceramics and metal materials. Carbon implants and rods are included in this group. Manufacturing includes casting, machining, and crystalline growth.

Tubular implants are made primarily of synthetic nonabsorbable materials. They are manufactured as extrusions or on tubular mandrels, creating seamless forms. Tubular implants are commonly coated to improve longevity and enhance biocompatibility.

Meshes are used primarily for hernia repair. They are available in absorbable and nonabsorbable woven forms and are therefore porous. Absorbable forms include polyglactin and polyglycolic acid. Nonabsorbable forms are commonly manufactured from polypropylene, polytetrafluoroethylene, and polyesters, but carbon fibers and metal meshes (of stainless steel and titanium) have also been used. Products are selected on the basis of the amount of material needed and the filament structure, including strength, pore size, long-term stability, and stiffness.7 Meshes should be used only in clean wounds because of the risk of chronic infection, fistula formation, and extrusion.

Suture materials are made from natural materials and synthetic polymers. They are manufactured as single-strand monofilaments, twisted or braided multifilaments, and staples. They are available as either absorbable or nonabsorbable products. Sutures are used primarily to appose tissues until the healing process maintains normal structural integrity, and to ligate blood vessels. Knowing the advantages and disadvantages, as well as the biologic and physical properties of each material, allows the surgeon to make knowledgeable choices for selecting the material that suits the intended need.

Organic Absorbable Materials

Surgical Gut
Surgical gut (the word is derived from intestine) is made from the submucosa of sheep or the serosa of cattle. It is a multifilament structure that is machine-ground and polished to resemble a monofilament suture. Chromium salts are used to increase strength and decrease the absorption rate of the material. It is phagocytized by macrophages at a variable rate and incites an inflammatory reaction with increased fibrosis at the site. The material has good handling characteristics, but it has poor knot security and may come untied as it swells with fluid exposure. As a result of the bovine spongiform encephalopathy (BSE) crisis, catgut is no longer used in human surgery and may not be manufactured in the future.

Collagen
Collagen is a multifilament suture processed from bovine flexor tendon and treated with formaldehyde or chromium salts, or both. Its characteristics and properties mirror those of gut, but its source and processing simplicity are advantageous. Collagen is also available as a hemostatic sponge. However, the BSE crisis that affected the use of catgut will certainly affect the use and production of this product.

Small Intestine Submucosa
Small intestine submucosa (SIS) is a denatured product from swine. The denaturing process leaves an extracellular matrix (ECM) that is 90% collagen. The ECM contains selected cytokines and signaling molecules, including fibroblast growth factor, transforming growth factor, and endothelial cell growth factor. The material is paper-like when dry but consists of approximately 90% water when moistened. It acts as a scaffold for regeneration of many body tissues and then is degraded and reabsorbed (see Chapter 26).

Synthetic Absorbable Materials

Poliglecaprone
Poliglecaprone is a monofilament absorbable copolymer of glycolic and lactic acid. It is absorbed by hydrolysis in 180 days. Tensile strength is maintained for 28 to 56 days. Its strength before implantation exceeds that of nylon or polypropylene and it has good knot security. It has poor handling characteristics when compared with braided absorbable materials, primarily because of its stiffness and memory. Poliglecaprone is superior to nylon and polybutester for tendon repair and has a wide spectrum of use in veterinary medicine.

Polylactic Acid
Polylactic acid and its L-isomer are used to form absorbable orthopedic rods and screws. The implants absorb slowly, with appreciable loss of strength in 2 to 3 months. Absorption is initially by hydrolysis, commencing with phagocytosis. Predrilling is required prior to implantation because of the poor torsional strength characteristics of the material.

Polyglycolic Acid
Polyglycolic acid is a braided multifilament polymer of glycolic acid. It is absorbed by hydrolysis in 100 to 120 days. Degradation products have some antibacterial effect. Tensile strength is maintained for 14 to 28 days. Its strength before implantation exceeds that of nylon or polypropylene and it has good knot security. It has poor handling characteristics when compared with braided absorbable materials, primarily because of its stiffness and memory. Polyglycolic acid is used in manufacturing suture materials, staples, surgical mesh, implants, and orthopedic pins.

Polydioxanone
Polydioxanone is a monofilament polymer of paradioxonane. It is absorbed by hydrolysis in 180 days. Tensile strength is maintained for 28 to 56 days. Its strength before implantation exceeds that of nylon or polypropylene and it has good knot security. It has poor handling characteristics when compared with braided absorbable materials, primarily because of its stiffness and memory. Polydioxanone is superior to nylon and polybutester for tendon repair and has a wide spectrum of use in veterinary medicine.

Polyglyconate
Polyglyconate is a monofilament copolymer of glycolic acid and trimethylene. It is absorbed by hydrolysis starting at 60 days and completed by 180 days. Its effective strength after implantation is superior to that of all other absorbable sutures. It has good handling characteristics and the best knot security of the absorbable sutures. Polyglyconate is superior to nylon and polybutester for tendon repair and has a wide spectrum of use in veterinary medicine.

Organic Nonabsorbable Materials

Silk
Silk is a braided multifilament structure made from raw silk spun by the silkworm. It has excellent handling characteristics and knot security. Although it is classified as a nonabsorbable suture, it loses tensile strength over time and is slowly absorbed over several years. It is used in most body tissues as a ligature, and it is commonly used in plastic, cardiovascular, and ophthalmic surgery. The material does not incite an inflammatory condition and may potentiate infection.

Silk-based implants for reconstruction of the Achilles tendon or of the cruciate ligaments were described as early as in the late 19th century, but reports of adverse reactions including inflammation and immune responses terminated their use. Novel purification protocols of the native silk
absorbed before failure. Similarly, porous matrices formed high-performance fibers such as Kevlar in terms of energy natural polymers and most synthetic materials, rivaling even silks in fiber form exceed those of all other biocompatible properties of silks because of their other advantageous properties—the mechanical properties of silks in fiber form exceed those of all other natural polymers and most synthetic materials, rivaling even high-performance fibers such as Kevlar in terms of energy absorbed before failure. Similarly, porous matrices formed from these proteins exhibit a combination of mechanical properties that exceed other polymeric biomaterials. These impressive mechanical properties, along with established biocompatibility and slow degradability, render silk fibrin an interesting biomaterial for further exploration of orthopedic applications.

Cotton
Cotton is a multifilament, nonabsorbable material derived from natural cotton fiber. The material slowly loses tensile strength over a period of 6 months to 2 years. However, the material gains tensile strength and knot security when wet. Cotton has a strong capillary action, is tissue reactive, and may potentiate infection. Today there is little use for cotton in equine practice, except as bandage material.

Synthetic Nonabsorbable Materials
Polyamides
Polyamides are available in two forms as synthetic non-absorbable surgical implants: nylon and caprolactam. Nylon is a mono- or multifilament fiber that is relatively inert and has no capillary action in its monofilament form. It loses about 30% of its tensile strength over a period of 2 years. As a multifilament suture, it retains no tensile strength after 6 months. Degradation products of the material have potent antimicrobial activity. The incidence of infection in contaminated tissues containing monofilament nylon is very low. Poor handling characteristics and knot security are related to its memory. Sharp suture tags (ends) may be irritating to surrounding tissue. Caprolactam is a coated multifilament suture material with biologic properties similar to nylon. However, caprolactam is enclosed in a smooth sheath of proteinaceous material and should not be buried under the skin, as the coating degrades and can incite a severe inflammatory reaction with excessive swelling and subsequent sinus tract formation.

Polyester
Polyester (Dacron) is a nonabsorbable, multifilament, synthetic fiber made from polyethylene terephthalate. Polyester is widely used as a woven vascular prosthesis and is available as a braided suture material. The material is strong, loses little strength after implantation, and is useful in slowly healing tissues. It is capable of eliciting more severe tissue reaction than other synthetic nonabsorbable suture materials. A polybutester coating improves handling characteristics, but it reduces knot security, requiring multiple throws to safely anchor the material. The material should not be used in contaminated wounds, as bacteria incorporated within the braids are isolated from antimicrobial and phagocytic cell activity, leading to chronic drainage and sinus tract formation.

Polybutester
Polybutester is a monofilament synthetic copolymer of polybutylene and polytetramethylene. The material displays good handling characteristics and knot security. Polybutester demonstrates a high degree of elastic stretch under low loads, and it is good for wounds where swelling is anticipated, as the material does not cut through the tissue. It is nonreactive in tissues and is applied in the repair of slowly healing wounds.

Polypropylene
Polypropylene is a nonabsorbable suture made from polypropylene plastic. It has the greatest strength of the synthetic nonabsorbable materials, with no appreciable strength reduction after implantation. Polypropylene is one of the most difficult sutures to handle because of its stiffness, slickness when wet, and material memory. It is one of the most inert and least thrombogenic suture materials available and is therefore used frequently in vascular surgery. Knot quality is marginal unless force is applied to the material, creating interlocking of fibers. Polypropylene is used as implantable mesh and as suture material.

Polyethylene
Polyethylene is a thermoplastic polymer, resistant to inorganic chemicals and to acidic and alkaline environments. The material's low coefficient of friction, its high-density formulation, and its excellent wear resistance make the product suitable as a prosthetic implant. Low-density polyethylene is used for catheters. The material has to be sterilized with ethylene oxide or gas plasma because of its low melting point.

Polytetrafluoroethylene
Polytetrafluoroethylene (Gore-Tex or Teflon) is a copolymer formed by the reaction between polyethylene and fluorine. It is relatively inert with a low coefficient of friction and has uses as vascular graft material, as a blood vessel replacement device, as implantable mesh material, and as a coating for prosthetic joint implants.

Polyurethane
Polyurethane is used as a polymer coating for implants because of its low thrombogenicity. This coating is fabricated onto implant device housings or into tubular mandrels. Its low melting point restricts it to ethylene oxide or gas plasma sterilization. An adhesive urethane membrane is commercially available for use in wound management.

Polyoxymethylene
Polyoxymethylene is a thermoplastic polymer that was used as a hip joint component. Extremely toxic metabolites
leaching from the wear surfaces resulted in severe inflammation and tissue necrosis. Presently, the material is used only as orthopedic washers because of its high creep resistance.

**Polyvinyl Chloride**
Polyvinyl chloride (PVC) is an organochloride polymer used extensively in cannula and catheter production. A diphthalate compound is added to polyvinyl chloride to increase flexibility. However, body fluid exposure leaches out additives, returning stiffness and rigidity to the material. These products should not be exposed to ethylene oxide sterilization as the gas adheres to the material, causing hemolytic reactions upon tissue exposure.

**Silicone**
Silicone is an organosilicon polymer that is very biocompatible. Because of their low thrombogenic properties, these products are often placed in contact with blood. It is one of the most widely used implantable materials and is easily fabricated into an assortment of steam-sterilized shapes and sizes. Sustained-release antibiotic coatings, minimizing infection, can be applied to the material for prolonged tissue contact.

**Polymethylmethacrylate**
Polymethylmethacrylate (PMMA) is formed by mixing powdered methyImethacrylate with the liquid polymer dimethyltoluidine. As the mixture polymerizes, an exothermic reaction occurs and forms PMMA. The initial reaction may lead to necrosis of exposed tissues. Although it is described as relatively inert, a fibrous tissue capsule usually forms around the implant. The primary use of PMMA is as cement for implanting metal prosthetics. It has also been used for bone-plate luting, increasing contact between the plate and bone. Antibiotics may be mixed in with the material to provide a sustained antimicrobial action, to decrease the chance of infection.

**Stainless Steel Sutures**
Stainless steel (SS), titanium, and other metal alloys used as orthopedic implants are discussed in detail later—the description here pertains to SS suture material. Steel is an alloy of iron and is processed as suture in monofilament and multifilament forms. It has the greatest tensile strength and knot security of all sutures, and SS is nearly biologically inert. SS sutures are indicated for tissues that heal slowly. To preserve knot security of all sutures, and SS is nearly biologically inert. SS sutures are indicated for tissues that heal slowly. Presently, the material is used only as orthopedic washers because of its high creep resistance. For multicomponent devices such as plates and screws, it is not advisable to mix SS and titanium implants, because an accelerated form of corrosion known as galvanic corrosion can occur. Implant SS may be used in the annealed or softest condition for reconstruction plates that are highly contoured or for cerclage wire that may be subjected to a large amount of twisting and torsional deformation. The alloy may also be supplied in the cold-worked or moderate-strength condition to resist the stress loading encountered by bone plates and bone screws. Cold-working is a metalworking operation that permanently deforms the material at room temperature to increase construct strength, usually by reducing the cross-sectional area by drawing or rolling. Small-diameter products such as K-wire, Schanz screws, and Steinmann pins may be fabricated from extra-hard or highly cold-worked material with a very high tensile strength (greater than 1350 MPa) for improved bending resistance. Relative tensile property requirements according to ASTM F 138 specification are shown in Table 9-2.

The excellent corrosion resistance of stainless steel is primarily a result of a chromium oxide film known as the passive layer, which is present on the surface. Chemical passivation in nitric acid is a commonly used method of surface finishing for stainless steel implants. Immersion in 20 to 45 volume-percent nitric acid passivation solution removes surface contaminants such as cutting tool transfer films, heat treat oxide, imbedded particles, and burnedin lubricants. The passivation process restores maximal corrosion resistance but does not affect part dimensions.

Electropolishing is another surface treatment that consists of applying an electric current to an implant immersed in a special formulated chemical solution under specified conditions.
The treatment removes a microscopic amount of metal, decreases the surface roughness of the implant, provides a low coefficient of friction, improves corrosion resistance, and creates a chemically passivated surface (Fig. 9-1). For certain applications, some implants may be shot-peened before electropolishing. The implant surface is subjected to high-velocity impaction by metallic or ceramic particles under well-defined conditions. Shot peening produces a roughened surface with increased residual compressive stress for enhanced fatigue life.

Implant-quality SS is completely nonmagnetic in all conditions, and implants may be subjected to magnetic resonance imaging (MRI) procedures. AO stainless implants will not exhibit torsional movement, displacement, or heating during MR scans. However, signal artifact may obscure complete MR visualization in the vicinity of the stainless implant because of the high iron content (approximately 62 weight-%). The 15% nickel content may provoke a metal sensitivity reaction and is responsible for about 90% of the metal allergies that are clinically observed in people. Repeated steam autoclaving will not disrupt the passive film or alter the mechanical properties of stainless steel implants.

**Titanium**

Commercially pure (CP) titanium, also known as unalloyed titanium, is available in five implant compositions designated Ti grade 1 ELI, 1, 2, 3, and 4 according to ISO and ASTM implant industry standards. The extra low interstitial (ELI) composition has the lowest content of nitrogen, carbon, iron, and oxygen. Each grade in the annealed condition has a different combination of tensile strength and ductility. The strength increases and the ductility decreases as the grade changes from the lowest designation (grade 1 ELI) to the highest designation (grade 4). Minimum properties for annealed CP titanium bar according to industry standards are shown in Table 9-3. Cold-working may be used to increase the strength of titanium that is designated grade 4B in ISO 5832-2, but a minimum of 10% elongation must be met. CP titanium has better biocompatibility than stainless steel, typically contains less than 0.05% nickel, and will not cause metal allergy reactions. Unalloyed titanium implants are recommended when metal sensitivity is preoperatively verified or when 316L stainless steel implants have provoked an allergic response.

Titanium also exhibits unique biocompatibility properties, which include soft tissue and bone adhesion to the implant surface. A major advantage of tissue integration at the surface has been the possibility of less bacterial colonization and reduced infection. Tissue adjacent to pure titanium implants becomes well vascularized, with less tendency toward capsule formation. The pitting and crevice corrosion resistance of titanium is superior to that of stainless steel. Titanium implant materials also have a lower density and a lower modulus of elasticity, and they provide

†Reduction of area: a measure of ductility (the original area minus the area after fracture divided by the original area).
significantly fewer MR artifacts than stainless steel. The density of titanium is 57% of the density of stainless steel and represents a weight reduction of nearly 50% when implants of similar dimensions are compared.

The modulus of elasticity is a constant physical property that describes the stress per unit strain in the elastic region. A material with a high modulus of elasticity transfers less stress from the implant to the bone. This may produce a condition known as stress shielding, which is not ideal because bone must be adequately stressed to consolidate properly during the bone healing stage. The modulus of elasticity of titanium is about 55% of that of stainless steel, and the low modulus is desirable because of increased stress transfer. The modulus consideration is less important for implants with a small cross-sectional area.

Titanium implants may have a special anodized surface finish that increases the thickness of the protective titanium oxide passive film. The titanium implants are immersed in a chemical solution, and a known electrical voltage is applied for a specified time. Visible light diffraction within the oxide film creates a distinct color that depends on the thickness of the oxide film. No pigments or organic coloring agents are present in the anodized titanium film. The titanium anodizing process is capable of producing a variety of colors that permit the design of color-coded implant systems (see Fig. 9-1). Multiple steam sterilization cycles will not significantly change the appearance of anodized titanium implants. However, fingerprint contamination from skin contact should be avoided when handling the implants between autoclave cycles. Gloved handling of anodized titanium implants prevents the discoloration of isolated areas during steam autoclaving.

Titanium Alloys

Titanium–6 aluminum–4 vanadium alloys, which have approximately 6% aluminum and 4% vanadium, are available in two compositions that are identified as Ti-6Al-4V or Ti-6Al-4V ELI. Another titanium alloy widely used as an AO implant material contains titanium, 6% aluminum, and 7% niobium and is identified as Ti-6Al-7Nb. Unique characteristics of titanium alloys include higher tensile strength capability, lower ductility, similar modulus of elasticity, and equivalent density when compared with commercially pure titanium. Important physical properties of CP titanium, titanium alloy, and stainless steel are compiled in Table 9-4.

Data on anodic polarization, pitting, and stress corrosion cracking indicate that Ti-6Al-7Nb is an extremely corrosion-resistant alloy. Unalloyed titanium and titanium alloys have well-documented notch sensitivity properties. Notch sensitivity is a term that describes the relative effect that local irregularities or stress raisers have on mechanical properties. The notch sensitivity resistance of implant quality stainless steel is similar to that of unalloyed titanium and somewhat better than that of conventional titanium alloys. Titanium-base biomaterials are not classified as notch-sensitive materials on the basis of notch tensile data that has been published. Some newer beta titanium alloys such as Ti-15Mo actually have improved notch sensitivity properties when compared with stainless steel. Implant design and manufacturing methods can influence the notch sensitivity resistance, and clinical factors such as surgical technique and handling must also be considered.

Titanium alloys may be color anodized in the same manner as CP titanium. The major difference is that the anodized film is an oxide mixture composed of thermodynamically stable oxides (i.e., TiO₂ + Al₂O₃ + Nb₂O₅). Retrieval analysis of human hip joint prostheses concluded that the Ti-6Al-7Nb alloy is extremely biocompatible, as evidenced by osseous integration at the implant surface.

Cobalt-Base Alloys

Cobalt-base alloys are used primarily for prosthetic implants such as total hips, total knees, and total disc replacement. Co-26Cr-6Mo is the predominant alloy that is fabricated for total joint applications. The nickel content of this alloy is typically less than 0.5%, and nickel sensitivity reactions have not emerged as a clinical problem. This alloy may be hot forged into complex shapes, the tensile strength can exceed 1170 MPa, and the wear resistance is outstanding. Overall, corrosion resistance is considered to be superior to that of stainless steel but inferior to that of titanium.

Other implantable cobalt alloys have been used for specialty trauma products such as orthopaedic cables, Kirschner wires, and implantable distractor components. Unique properties of cobalt-base alloys include a high modulus of elasticity, which may be 25% greater than stainless steel. Cold-working increases the strength of cobalt-base alloys, and thermal aging heat treatments can significantly increase the yield and ultimate tensile strength. The majority of cobalt-based alloys contain greater than 10% nickel, which may provoke a nickel allergy reaction. The excellent

corrosion resistance of the cobalt-base alloys is predominantly the result of the chromium content, which typically exceeds 18%. Chromium and cobalt are considered metal sensitizing agents, but the clinical incidence of sensitivity reactions is relatively rare when compared with nickel.21

METALLIC INSTRUMENT MATERIALS
Stainless Steel

The types of stainless steel that are used for instruments can be classified according to their microstructure, magnetic attraction, corrosion resistance, and hardness. A general comparison of commonly used stainless instrument materials is shown in Table 9-5.38

The martensitic (the word describes the type of microstructure associated with 400 series stainless steel, which is magnetic and has moderate corrosion resistance) compositions contain a minimum of 12% to 18% chromium, a medium to high carbon content, and other minor elements. Common types of martensitic alloys of the 400 series of stainless steel include 420A, 431, and 440B, and each grade has an equivalent Deutsches Institut für Normung (DIN) designation. The alloys are fabricated into various instruments in the soft condition and heat-treated to develop full mechanical properties. Heat-treating39 consists of a hardening process that transforms the microstructure by heat in the range of 930° to 1150° C, followed by a controlled quench in air or a liquid. The hardened structure must be tempered at an intermediate temperature of 150° to 370° C to develop the final optimal properties.39 For a given alloy, the hardness typically decreases as the tempering temperature increases. Martensitic alloys have high hardness and wear resistance. These alloys are used mainly for cutting instruments such as drills, taps, countersinks, reamers, chisels, and bone-cutting forceps, and for noncutting applications such as screwdriver blades and wrenches.

Precipitation-hardenable (PH) stainless steels contain substantial amounts of chromium, nickel, and copper, plus controlled levels of secondary elements.39,40 The PH compositions are usually fabricated in the annealed condition, and the heat treatment is finished in a one-step aging treatment that promotes a hardening mechanism as a result of precipitation of a secondary strengthening phase within the martensitic matrix structure. Various age-hardened conditions (e.g., H900 and H950) are available, and the final hardness is inversely related to the age hardening temperature. PH stainless steels are used for a variety of noncutting instruments that require a moderate hardness level. The PH grades do not contain a high carbon content, so edge retention and wear resistance are inferior when compared with the 400 series martensitic compositions. A commonly used alloy contains 17% chromium plus 4% nickel (17-4PH) and is also identified as type 630.

Austenitic (this type of microstructure is nonmagnetic and has high corrosion resistance) stainless steels are known as the 300 series 40 and usually contain 16% to 18% chromium and 8% to 10% nickel. The low carbon grades such as 304L (L indicates low carbon) meet a compositional requirement of a maximum of 0.03% carbon. Other major elements may be added to improve the microstructure stability and corrosion properties. The 300 series stainless steels have excellent corrosion resistance and may be strengthened by cold-working, but they do not have outstanding cutting or wear properties because of the low carbon content. The austenitic alloys, except for 316 and 316L, which contain 2% to 3% molybdenum, also become slightly magnetic as the amount of cold-work increases. Some of the austenitic SSs can be cold-worked to a very high tensile strength and may be used for some noncutting applications including drill guides, clamps, hollow sleeves, springs, and washers. Some typical stainless steel instrument materials38 are compared in Table 9-6.

Aluminum

Aluminum is available in various purities, and a composition frequently used for bone plate or rod templates is known as grade 1100. This grade of aluminum meets a minimum aluminum content of 99.00%, and it is supplied in the soft annealed condition (O temper). Aluminum templates are low in strength, highly ductile, nonmagnetic, and lightweight. They may be color anodized to complement color-coded instrument systems. The anodizing treatment for aluminum is different from the electrolytic anodizing treatment used for titanium. The anodized color produced on aluminum is a result of an organic dye that is infiltrated into the aluminum oxide surface. The surface is then chemically sealed, and other additives may be incorporated into the coating. Additional details regarding surface treatments for aluminum are covered later.

Aluminum Alloys

Aluminum alloys have increased strength and less ductility compared with pure aluminum. The alloys are grouped according to 2xxx through 8xxx identities, depending on the major alloying elements that are present. Aluminum alloy compositions that are frequently used for instruments include 2024, 5052, and 6061. The alloys are usually produced to a designated temper, which covers the heat-treating and/or other finishing operations that define the supplied metallurgical condition. A 5052-H32 designation indicates a 5022 alloy with an H32 temper (strain hardened/stabilized/quarter hard). Another common designation is 6061-T6; the T6 temper refers to solution-heat-treated plus artificially aged condition. Aluminum alloys have been used for depth gauges, IM nail insertion instruments, hollow external fixation rings, graphic case modules, and screw racks. Typical gauges, IM nail insertion instruments, hollow external fixation rings, and screw racks. Titanium alloys such as Ti-6Al-4V or Ti-6Al-7Nb may occasionally be used for noncutting instrument applications. External fixation components have been designed to take advantage of these properties. Cobalt-base alloys have a high modulus of elasticity, which is beneficial for small-diameter guide wires and aiming instruments that require high stiffness.

Other

Titanium alloys such as Ti-6Al-4V or Ti-6Al-7Nb may occasionally be used for noncutting instrument applications. The nonmagnetic alloys have high strength and low weight, and they may be anodized for color-coded systems. External fixation components have been designed to take advantage of these properties. Cobalt-base alloys have a high modulus of elasticity, which is beneficial for small-diameter guide wires and aiming instruments that require high stiffness.

CERAMICS (M. BOHNER)

There are two main classes of ceramic bone substitutes (CBS): calcium sulfates (CaS) and calcium phosphates (CaP). Both families consist of several chemical compounds representing more than a dozen compositions (Table 9-8).

The first CBS that was used in vivo was β-hemihydrate CaS (β-CaSO₄·½H₂O). Addition of water to this material elicits an exothermic reaction, with the end product being a set form of gypsum (CaSO₄·2H₂O). Beside β-CaSO₄·½H₂O and gypsum, there are two other CaS of less clinical importance, which are α-CaSO₄·½H₂O and CaSO₄·2H₂O.

Hydroxyapatite [Ca₅(PO₄)₃OH], β-tricalcium phosphate [β-Ca₃(PO₄)₂], and their composites (commonly called biphasic calcium phosphates) are the most common CaP bone substitutes. However, apatites can be synthesized with various structures and compositions. Additionally, many other calcium phosphates, such as dicalcium phosphate dihydrate and octacalcium phosphate, are available and have been used in vivo.

To simplify matters, there are presently two classes of CaP: low- and high-temperature CaP. Low-temperature CaPs are obtained at room temperature, through either a setting (i.e., hardening; see later) or a conversion reaction. These CaPs can be found in vivo, and they typically have a small average crystal size and a large specific surface area (up to 100 m²/g for apatites). High-temperature CaPs are obtained by sintering reactions (i.e., heating at temperatures higher than 700° to 800° C). As high-temperature CaPs are easier to synthesize than low-temperature CaPs, most commercial products (e.g., chronOs, the AO standard product) are
obtained via sintering reactions. However, low-temperature CaPs, such as dicalcium phosphate dihydrate or precipitated apatite, are likely to become more important in the future, because these compounds are more similar to the CaP present in the body.

Hydraulic cements are obtained via dissolution-precipitation reactions in an aqueous solution. For example, $\beta$-CaSO$_4 \cdot \frac{1}{2}$H$_2$O dissolves in water and gypsum crystals nucleate and grow. If the powder-to-liquid ratio is large enough (typically greater than 2 g/mL), gypsum crystals grow close enough to entangle and hence provide mechanical stability to the resulting hardened compound. The setting reaction is generally exothermic, but the rate of heat release is too low to cause biocompatibility problems. Hardened cement blocks are nanoporous or microporous, and their porosity is typically in the order of 40% to 50% of the volume.

Whereas plaster of Paris has been known for ages, the discovery of CaP cements is recent. The first products were introduced a decade ago. Many compositions have been proposed, but the end product of the reaction can only be brushite (e.g., chronOS Inject) or an apatite (e.g., Norian SRS). As a result, the terms brushite cements and apatite cements are used. Because of their higher solubility, brushite cements tend to resorb much faster than apatite cements (see later).

Porosity

The porosity strongly influences the mechanical and biologic properties of CBSs. Generally, there are two types of pores: micropores and macropores (Fig. 9-2). Micropores typically have a diameter in the size range of 1 to 10 $\mu$m. Micropores have been considered to promote ceramic resorption, but the amount of scientific data is very scarce. It is therefore not possible to define an optimal micropore size or volume fraction. However, micropores are essential to prevent crack propagation and hence should be a standard feature of CBSs. A practical advantage for the clinician is that a microporous CBS can be shaped with a blade. Presently, only few products contain a significant fraction of micropores, one of them being chronOS (Synthes, Inc, Paoli, Pa).

Macropores typically have a diameter in the size range of 50 to 2000 $\mu$m. Macropores enable blood vessel and cell ingrowth, hence promoting bone ingrowth and short resorption times.

Mechanical Properties

Compressive strengths as high as 100 MPa (i.e., almost as high as that of bone) have been indicated for some CBSs. Unfortunately, CBSs are ceramics and therefore inherently brittle. As a result, tensile strengths are typically 5 to 20 times lower than compressive strengths, and shear properties are miserable. Therefore, CBSs can break at very small loads (much lower than the indicated average mechanical strength) and hence should be used in combination with an internal or external fixation device.

Many factors, such as porosity, chemistry, and crystal or grain size, influence the mechanical properties of CBSs. Typically, an increase in porosity decreases the mechanical properties of a material exponentially. As mentioned before, micropores decrease the brittleness of a CBS. Furthermore, the least soluble CBSs (e.g., hydroxyapatite) tend to have the
highest mechanical properties. Finally, a small crystal or grain size favors large mechanical properties.

**Forms**

CBSs are available in various forms: granules, macroporous blocks, hydraulic cements, and putties (paste). Each of these forms has specific advantages and disadvantages. Granules can be filled into any defect, but this procedure is often cumbersome, and granules can migrate. Bone formation and tissue ingrowth are both optimal because of the availability of blood vessels and cells, which invade the space between the granules. Blocks, such as cylinders, wedges, and prisms, are difficult to place in complicated defect geometries. However, blocks are mechanically stable and have an optimal porous structure that enables fast blood vessel and cell ingrowth. Hydraulic cements are often injectable. As a result, these cements are easy to apply into any defect and can be shaped. Moreover, cements harden with time, hence providing a stable (but not load-bearing) defect-filling material. However, the cements presently available are not macroporous. Therefore, resorption takes place slowly, layer by layer.

The latest form of CBSs is the so-called putty, a term that means that the CBS is a thick paste. The nature of this paste varies from one producer to another. Some putties are also a hydraulic cement and thus behave like a cement. But traditionally, putties consist of a mixture of a gel and granules. The advantage of putties is that they are easier to apply than granules. Moreover, granules do not move out of the defect as easily when accompanied by a gel.

**Biologic Behavior**

The mechanisms of resorption of CBSs vary widely depending on their solubility. CaS dissolves in vivo because body fluids are undersaturated in CaS. As a result, a change of blood supply or sample volume is expected to modify the dissolution time. A large gap occurs between implant and bone. Typically, the amount and quality of the bone formed in the defect filled with CaS is poor: it consists of very narrow and small trabeculae, which tend to resorb with time. On the other hand, traditional CaPs, such as β-tricalcium phosphate (β-TCP), hydroxyapatite, and their composites, are insoluble in body fluid (e.g., in serum). This low solubility leads to an osteoclast-mediated
resorption, the rate of which depends on the composition. Whereas β-TCP is typically resorbed within a year, hydroxyapatite is practically nonresorbable (Fig. 9-3). However, for all traditional CaPs, a direct apposition of bone on the ceramic surface is observed. Other calcium phosphates, such as dicalcium phosphate dihydrate (DCPD), have an intermediate solubility and hence an intermediate resorption rate. In that case, resorption occurs primarily via macrophages. Moreover, often a small gap between bone and implant develops. This gap is typically filled with osteoid tissue. Apatite cements are slowly resorbable, whereas hydroxyapatite is practically nonresorbable. This apparently peculiar difference is caused by a variation in crystal size: apatites obtained from hydraulic cements are nanosized, whereas sintered hydroxyapatite is microsized. Actually, apatite cements are soluble and hence have a resorption rate similar to that of β-TCP.

Many studies have been conducted to determine an optimal pore size for bone ingrowth and resorption rate. However, the results are not so conclusive for two main reasons: (1) it is difficult to synthesize ceramics with perfectly controlled geometries, and (2) most in vivo studies have considered only few geometries (e.g., one or two) at few implantation times (e.g., one or two). Nevertheless, it could be shown that a pore diameter in the range of 100 to 1000 µm is adequate, the macropores should be interconnected, and the size of the interconnections should be larger than 50 µm. A recent study applied a theoretical approach to determine an adequate pore structure to minimize the resorption time; it revealed that a pore diameter in the range of 200 to 800 µm is optimal, but that this depends on the size of the bone substitute, with larger pieces requiring larger pores.

ADHESIVES
Cyanoacrylate
Cyanoacrylate monomers are clear, colorless liquids with low viscosity and high reactivity. Reactivity is demonstrated by instantaneous polymerization in the presence of moisture, creating a thin, flexible polymer film that adheres to tissue. The film creates a mechanical barrier that is water resistant and resistant to infection, and that maintains a moist wound environment. Two formulations are available for medical application. The butyl formulation is used primarily as a topical bandage, whereas the octyl formula can be used to appose skin edges. Strength of closure is comparable to that of subcuticular skin sutures. Although the octyl formulation is less cytotoxic than the butyl form, application is for topical use only. Cyanoacrylates are not biodegradable.

Fibrin Glues
Fibrin glues consist primarily of a combination of thrombin and fibrinogen. Autologous glue is composed of fibronectin, thrombin, aprotinin, fibrinogen, factor XIII, and calcium chloride. Autologous fibrin glue can be created by collecting plasma from the patient prior to surgery and then polymerizing an artificial clot. A commercial bovine source is available, but autoimmune reactions are a concern. This compound can be used as a sealant or as a hemostatic agent. Fibrin glues stick to and seal tissue. They have been used to seal leaks in lung, dura, intestine, liver, and spleen. The material is broken down by fibrinolysis.

Glutaraldehyde Glue
Glutaraldehyde glue is a relatively new agent that contains gelatin, resorcinol, formaldehyde, and glutaraldehyde, and it is essentially albumin mixed with adhesion compounds. The glue has a half-life of about 30 days and is used in people as a cardiovascular and pulmonary adhesive. Long-term outcomes are presently unavailable.

Polyethylene Glycol Polymers
Polyethylene glycol polymers are hydrogels that are used for tissue adhesion. This product is a water-soluble agent. It uses light to photopolymerize the substance and activate adhesion. Application is a complicated technique. The compound is degraded over a period of 3 months.
TOPOCAL HEMOSTATIC AGENTS

Selected product formulations considered either adhesives or hemostatic agents can perform dual functions. They can be used as adhesive glue or as a hemostatic agent. These products are biocompatible, biodegradable, and easily applied. They incite minimal antigenicity and do not inhibit normal healing.73,74

Collagen-Based Adhesive

Collagen-based adhesive is relatively new but demonstrates great potential. The compound is made from a combination of bovine thrombin and freeze-dried bovine collagen powder that is rehydrated, forming a gelatin matrix. On contact with fluids, the gelatin swells, providing a tamponade effect as well as forming a clot matrix, and then delivers fibrinogen to the area. Autologous plasma can be added to the formulation for a better result.

Polysaccharide Powder

Polysaccharide powder is a plant-based microporous derivative. Applied to a bleeding surface, the hydrophilic particles concentrate platelets, red blood cells, thrombin, and fibrinogen, accelerating the natural hemostatic process. Effective hemostasis is rapid.

Purified Gelatin Sponge

A purified gelatin sponge is applied topically to oozing capillaries, achieving hemostosis. On contact with blood, the gelatin absorbs fluid many times its weight, providing a tamponade effect while promoting platelet aggregation. The porosity of the gelatin particles provides a matrix for fibrin deposition and subsequent fibroblast migration. The material is absorbed by phagocytosis over a period of 4 to 6 weeks. Gelatin sponges should not be placed in contaminated wounds as they potentiate infection.

Oxidized Regenerated Cellulose

Controlled oxidation of regenerated cellulose forms a knitted mesh fabric that can be applied to a bleeding surface. Hemostasis is achieved by the formation of an artificial clot, independent of the inherent clotting pathways. The regenerated cellulose also has an affinity for hemoglobin and forms hydrated aggregates that plug exposed vessels. It induces minimal inflammation and fibrosis, and it is known to be bactericidal.

Collagen Absorbable Hemostat

Collagen absorbable hemostat consists of purified and lyophilized bovine collagen containing an abundance of type II collagen, manufactured in a spongeliike pad. Subendothelial type II collagen is known to attract platelets, aggregating on the material and releasing coagulation factors that initiate clot formation. Pads are highly cross-linked, pliable, and absorbable. Autoclaving inactivates the product. Absorption occurs by phagocytosis and enzymatic degradation.

Bone Wax

Bone wax consists of a mixture of beeswax, paraffin, and isopropl palmitate. It controls bleeding from bony surfaces by acting as a mechanical barrier, it can be moderately antigenic, it is nonabsorbable, and it can inhibit orthogenesis, delaying the healing process. Bone wax may cause a mild inflammatory reaction.

Sterilization refers to the complete destruction or elimination of vegetative bacteria, bacterial spores, viruses, and fungi, by physical or chemical methods. Antisepsis signifies the inhibition of the growth and development of microorganisms without necessarily killing them. Therefore, antiseptics can be applied to living tissues. Physical methods of sterilization include heat (thermal energy), which is the most commonly used type in veterinary hospitals, and filtration and radiation, which are usually applied in the industrial preparation of sterile materials. Ethylene oxide is the most widely used method of chemical sterilization, but physical methods are considered to be more uniformly reliable.

INSTRUMENT PREPARATION AND PACKING

Cleaning

Instruments cannot be sterilized until they are completely clean, because steam cannot penetrate materials such as oil, grease, dried blood, and other organic material. Ideally, an assistant should wipe every instrument used during surgery, before it is replaced on the surgery table, to prevent blood drying on the instrument. Once the instruments are returned to the sterilizing room, they are prepared for autoclaving by immediate rinsing in cold water to remove any remaining blood and debris, after which they can be cleaned with a moderately alkaline, low-sudsing detergent, or in an ultrasonic cleaner. Pre-rinsing in an enzymatic detergent solution is an acceptable alternative to manual cleaning. Enzymatic detergents used for cleaning medical devices (Enzol, Johnson & Johnson, New Brunswick, NJ; Endozyme, Ruho, Mineola, NY; Sterizyme, Anderson Products, Haw River, NC; and Metrizyme, Metrex Research Division of Sybron Canada, Ltd, Morrisburg, Ontario, Canada) help remove proteins, lipids, and carbohydrates, depending on the formulation. Many of the available enzymatic detergents have a minimum contact time of 2 to 5 minutes (Asepti-zyme, Huntingdon Lab, Ontario, Canada; Gzyme, Germiphene Corp, Brantford, Ontario, Canada; OptiM22, Virox Technologies, Mississauga, Ontario, Canada; and Metrizyme, Metrex Research Division of Sybron Canada, Ltd, Morrisburg, Ontario, Canada). After the instruments have been cleaned by these methods, they should be soaked in the oil known as instrument milk, which conditions the instrument surface and lubricates the joints. After an adequate air drying time, they are packed in wrappers that are permeable to steam but not to microorganisms.

Packing

All packs should be marked as to content, date of sterilization, and person responsible for assembling, and the pack should be stored for times appropriate for the material and the method of storage (Table 10-1). For muslin wraps, double layers and two wraps are recommended for each pack. Alternatively, pima cotton can be used, which is a more effective barrier than muslin because of the smaller pores.
pore size. Pima cotton wraps can be reused an approximate 75 times, after which so much fabric has been lost that no effective barrier against microorganisms exists. Crepe papers are preferred to noncrepe papers because of their superior durability and handling qualities, and because their safe storage times are longer than that of fabrics.

Instruments can also be sterilized in stackable containers of aluminum composite material (Fig. 10-1) that are dent resistant, available in a variety of sizes, easy to store and transport, and allow safe storage times of up to 1 year (AMSCO Sterilization Container System, STERIS Corporation, Mentor, Ohio). The aluminum composite increases the thermal conductivity of the container during drying to help ensure dry contents. The system is suitable for use in steam, ethylene oxide, and gas plasma sterilization. Three types of filters—cartridge (with internal chemical indicator), disc, or ceramic—are available for this system. The filter is retained in a filter access portal in the lid and base of the units by a retainer ring. Selection of the type of filter is determined by the sterilization cycle to be used, such as prevacuum steam, gravity steam, flash, ethylene oxide, or gas plasma.

Although pima cotton and crepe paper are well suited for instrument packs, these materials are rarely used to wrap single instruments. For this purpose, special sleeves have been developed that are paper on one side and clear cellophane on the other. The sleeves come in different sizes to allow the packing of instruments of different sizes. Also, different sizes are required because the instruments should be double wrapped. The ends of the sleeves are heat sealed. The sharp points of all instruments must be protected by plastic covers. The paper side allows penetration of steam, ethylene oxide, or gas plasma, and the cellophane side provides a view of the contents (Fig. 10-2). These single packs should be identified by date of sterilization and the person who packed it.

**Autoclave Indicators**

Autoclave indicator systems include chemical indicators that undergo a color change on exposure to sterilizing temperatures, and biologic indicators, such as heat-resistant bacterial spores (e.g., *Bacillus stearothermophilus*). These spores are extremely resistant to heat, and the indicator systems require a period of incubation after sterilization to ensure the absence of bacterial growth. An indicator tape on the outside of the pack provides no information about the sterility of the pack’s contents, so an additional indicator should be placed in the center of the pack. Many of the currently available indicators of sterility are more reliable than simple physical indicators, such as tape, because they indicate that both temperature and time are sufficient for providing sterility (Fig. 10-3), whereas tape merely indicates to the surgeon that the pack was subjected to heat.

PHYSICAL STERILIZATION

Thermal Energy

Dry heat kills by a combination of oxidation and removal of water, whereas moist heat kills by the coagulation of critical proteins. Moist heat sterilization can coagulate and denature cellular protein at lower temperatures than those required by dry heat and thus can decrease the temperatures and exposure times necessary for sterilization.2,3

Exposure time and temperature required to kill microbes are functions of their individual heat sensitivities, which vary with type of organism and the environment to which they are accustomed.3 For example, bacterial spores are more resistant than the vegetative form of the bacteria.3 Recommended sterilization times and temperatures are designed to kill all microorganisms, even those that are heat resistant (Table 10-2). Minimum guidelines are an exposure time of 15 minutes at 121°C (249.8°F) and 15 p.s.i. or 2 atmospheres of pressure in a steam autoclave. Because microbial death occurs in a logarithmic fashion, exposure time is as important as temperature. The greater temperatures and water saturation attained by pressurized steam allow for shorter sterilization times. Steam gives up its heat to materials to be sterilized by the process of condensation, and it is able to penetrate porous substances more rapidly than dry heat.3

Most autoclaves used in veterinary hospitals use steam pressure to drive air downward and out of the pressure vessel, in a process called gravity displacement4 (Fig. 10-4). Air displacement by steam is critical to achieve condensation on all surfaces, and air reduces the temperature of steam at any given pressure.3 Arrangement of trays or bowls within the autoclave must be such that air cannot be trapped by the downward progression of the steam, and bowls should be placed with their openings to the side or facing down.7,9 Also, packs should be loaded into the autoclave with a loose arrangement to ensure distribution and circulation of steam without the formation of air pockets9 (Fig. 10-5). Valves in cannulas should be left open to ensure adequate steam penetration.30 Because air trapped in closed, impervious

*Times are given for gravity displacement autoclaves. Extra time is required for pack contents to reach sterilization temperatures (heat-up time).
†Emergency sterilization is best accomplished in prevacuum autoclaves, which have shorter heat-up times required.
containers can inhibit steam penetration, items in glass tubes should be sealed with cotton plugs. Many newer or more sophisticated types of autoclaves use a vacuum to displace air from the materials to be sterilized. This allows shorter sterilization times but adds to the cost of the equipment. Other modifications use pulsed steam pressure and special valve systems to hasten air removal prior to sterilization. Prevacuum steam sterilizers evacuate air from the chamber before steam is admitted, so the time lag for complete air removal is eliminated and the problem of air entrapment is minimized. This system is well suited for “flashing” instruments.

It is also recommended that the steam sterilizer be periodically tested for functionality. The Bowie-Dick test can be used to prove that air removal and steam penetration were complete. The Steri-Record (gke-mbH, Waldems-Esch, Germany) provides two simulation tests for different applications, depending on the sterilization programs used. These Bowie-Dick simulation tests simulate hollow devices, such as trocars, which require more demanding air removal and penetration conditions than porous cotton. The indicator systems consist of a process challenge device (PCD) with an indicator inside. One of the systems is the Helix-PCD, consisting of a polytetrafluoroethylene (PTFE) tube and a metal test capsule holding the integrated indicator (Fig. 10-6). The second system is the Compact-PCD, consisting of an external plastic casing with a stainless steel coil inside that holds the indicator. To ensure proper functioning of the sterilizer, such a kit should be included in each sterilizer charge.

Filtration
Sterilization by filtration is used for air supply to surgery rooms (laminar flow ventilation), in industrial preparation of medications, and for small volumes of solutions in practice settings. The laminar air filtering system for surgery suites is discussed in Chapter 11. For fluids, two types of filters are commonly used—depth filters and screen filters. Screen filters function like a sieve to remove any microorganisms or particulate matter larger than the pore diameter of the screen. Depth filters trap microbes and particles by a combination of random absorption and mechanical entrapment.

Radiation
Sterilization by radiation is used in the industrial preparation of surgical materials that are sensitive to heat or chemical sterilization. The facilities required for ionizing radiation render them unsuitable for use in veterinary hospitals. Although radiation is suitable for items that cannot tolerate heat sterilization, it can change the composition of some plastics and pharmaceuticals.

CHEMICAL STERILIZATION
Ethylene Oxide
Ethylene oxide (EO) is the most commonly used agent in chemical sterilization. Because it is a gas, it rapidly penetrates packaging and items to be sterilized at temperatures tolerated by almost all materials. However, its use is limited by the size of the equipment, the time requirement, and concerns about toxicity. It is recommended for use only for items unsuitable for steam sterilization, including
laparoscopes, light cables, and camera heads. In fact, because of environmental concerns, ethylene oxide sterilizers are now required by law to be retrofitted with abaters that reduce more of the exhausts to water vapor. Despite the use of abaters, the Environmental Protection Agency has outlawed the use of EO sterilizers altogether in some areas. Gas plasma sterilizers are a logical replacement choice (see later).

Ethylene oxide is an alkylating agent that kills microorganisms by inactivation of proteins, DNA, and RNA, and it is effective against vegetative bacteria, fungi, viruses, and spores. It is supplied as a gas mixed with a carrier agent (Freon or CO₂) to reduce flammability. Mixed with air or oxygen, EO is explosive and flammable. Carbon dioxide is the preferred diluent because of environmental concerns about fluorinated hydrocarbon (Freon) release, although a tendency to stratify from carbon dioxide in storage containers could affect sterilization.

Sterilization by ethylene oxide is influenced by gas concentration, temperature, humidity, and exposure time (Table 10-3). The more sophisticated equipment for EO sterilization includes methods for temperature elevation to shorten sterilization times. Spores require time for humidification to allow optimal killing by ethylene oxide. The humidity should not be raised by wetting the materials to be sterilized, because ethylene oxide forms condensation products with water that may damage rubber and plastic surfaces. Also, the effectiveness of ethylene oxide sterilization may be reduced below the lethal point by condensation products with water that may damage rubber and plastic surfaces. Therefore, the materials to be sterilized, because ethylene oxide forms condensation products with water that may damage rubber and plastic surfaces. Also, the effectiveness of ethylene oxide sterilization may be reduced below the lethal point by condensation products with water that may damage rubber and plastic surfaces.

Because ethylene oxide penetrates materials more readily than steam, a wider variety of materials may be used in packaging items for sterilization and storage. Films of polyethylene, polypropylene, and polyvinyl chloride are commercially available, but nylon should not be used, because it is penetrated poorly by ethylene oxide. Positioning of packs is less critical than with steam, but loading and compression in the sterilizer can prevent adequate penetration.

After sterilization by EO, materials must be aerated to allow dissipation of the absorbed chemical (Table 10-4), because residual ethylene oxide can damage tissues. For example, inadequate aeration of endotracheal tubes sterilized by EO caused tracheal necrosis and stenosis in horses and dogs. Although some ethylene oxide chambers are equipped with mechanical aeration systems to reduce aeration times (Fig. 10-7), those commonly used in veterinary hospitals use natural aeration in well-ventilated areas. EO sterilization indicator strips should be used on the outside of surgery packs, and chemical or biologic indicators of ethylene oxide exposure are used inside. The 3M (St. Paul, Minn) Comply EO chemical integrators demonstrate a color change and migration on an absorptive strip in response to all the critical aspects of EO sterilization, such as EO concentration, relative humidity, time, and temperature. Safe storage times are 90 to 100 days for plastic wraps sealed with tape, and 1 year for heat-sealed plastic wraps.

Exposure to ethylene oxide can cause skin and mucous membrane irritation, nausea, vomiting, headache, cognitive impairment, sensory loss, reproductive failure, and increased incidence of chromosomal abnormalities. Ability to detect the gas by smell is lost after prolonged exposure. Ethylene chlorohydrin is a highly toxic degradation product of EO that is formed most readily in products that have been previously sterilized by radiation.

**Gas Plasma**

Gas plasma sterilization (Sterrad Sterilization System, Advanced Sterilization Products, a division of Johnson & Johnson Medical, Inc, Irvine, Calif) (Fig.10-8) allows short

Times are given for natural aeration and, where available, for mechanical aeration. Ethylene oxide sterilizers equipped for mechanical aeration produce significantly shorter aeration times (hours instead of days).

instrument turnaround time, has no recognized health hazards, and operates at a low temperature (less than 50°C). An aqueous solution of hydrogen peroxide is injected into the chamber and converted to gas plasma by radio waves that create an electrical field. In this field, hydrogen peroxide vapor is converted to free radicals that collide with and inactivate microorganisms. Gas plasma is suitable for heat- and moisture-sensitive instruments (rigid endoscopy lenses and instrument sets, objective lenses for microscopes, nonfabric tourniquets, medication vials, insulated electro surgery and cautery instruments, and metal instruments). Also, the process does not dull the sharpness of delicate microsurgical instruments. Gas plasma is unsuitable for flexible endoscopes, liquids, and items derived from plant fibers (paper products, linens, gauze sponges, Q-tip applicators, cast padding, wooden tongue depressors, gloves, and single-use items), because these materials absorb hydrogen peroxide and inhibit sterilization. Very long narrow lumens, lumens closed at one end, folded plastic bags, and sheeting are unsuitable for sterilization by gas plasma.

**Peracetic Acid**

Peracetic acid (PAA) is available under numerous brand names with different chemical formulations (Nu Cidex 0.35%, Johnson and Johnson; STERIS 0.20%, STERIS Corporation, Mentor, Ohio, and STERIS Limited, STERIS House, Basingstoke, Hampshire, UK; Anioxyde 1000, Clinipak Medical Products, Bourne End, UK; and Sekusept Aktiv, Ecolab Center, St. Paul, Minn). The STERIS Corporation has marketed STERIS 20 Sterilant Concentrate, a 35% peroxyacetic acid concentrate, for use in the STERIS System 1 (Fig. 10-9). An arthroscopic camera and telescope can be processed, rinsed, and dried in this system in a 20-minute cycle. It is routinely used to sterilize flexible endoscopes as well. A contact time of 10 or 15 minutes and a concentration of greater than 0.09% PAA are recommended for destruction of bacteria, fungi, viruses, and spores, if used manually. Compared with glutaraldehyde, PAA has a similar or even a better biocidal efficacy and is claimed to be less irritating for staff and safer for the environment. PAA does not fix proteins and therefore does not create a biofilm. It has the ability to remove glutaraldehyde-hardened material from biopsy channels, and its activity is not adversely affected by organic matter. Potential adverse effects are strongly linked to the pH value of the application solution, with minimal effects in a pH range of 7.5 or higher. PAA is less stable than glutaraldehyde, can be corrosive, and has a strong...
vinegar-like odor. Therefore, when using manual immersion methods, PAA should be used with adequate ventilation and personal protective measures. PAA also causes cosmetic discoloration of endoscopes, but without any functional damage if used manually; the STERIS System 1 sterilizer does not have this problem, however, as adequate rinsing is automatic. PAA is also expensive.8

**Electrolyzed Acid Water**

At present, two types of electrolyzed acid water (EAW) are available—electrolyzed strong acid water with a pH of less than 3 (e.g., CleanTopWM-S, CBC Medical Device Group, Duesseldorf, Germany) and electrolyzed weak acid water, with a pH of between 6 and 7 (e.g., Sterilox Technologies, Inc, Radnor, Pa).1 EAW is produced by using water and salt under electrolysis with membrane separation. The process generates hydroxy radicals that have a rapid and potent bactericidal effect. Additionally, the low pH (pH 2.7) and high oxidation-reduction potential (1 100 mV) are toxic to microorganisms.8 EAW breaks the bacterial cell wall and degenerates various inner components of the bacterium (including chromosomal DNA). EAW is nonirritating, has minimal toxicity, and is safe and inexpensive, but the bacterial effect is drastically decreased in the presence of organic matter or biofilm. Also, EAW is unstable, and the full disinfecting potential of EAW and its long-term compatibility for endoscopes remain to be examined.8

Sterilox, often referred to as superoxidized water, is a dilute mixture of mild oxidants at neutral pH derived from salt by electrolysis in a proprietary electrochemical cell. The primary active species is hypochlorous acid, an extremely powerful disinfectant completely nontoxic in the low, clinically effective small concentrations produced in Sterilox. Sterilox is generated on site, as needed, and stored no longer than 24 hours. The active agents decompose slowly to harmless species.8

**Chlorine Dioxide**

Chlorine dioxide (e.g., Tristel, Tristel Co, Ltd, Snailwell, UK; Dexit; and Medicide) is a powerful oxidizing agent and is active against nonsporing bacteria, including mycobacteria and viruses, in less than 5 minutes, and is rapidly sporicidal (10 minutes).8 Chlorine dioxide is more damaging to instruments and components than glutaraldehyde.8 Experience with chlorine dioxide has demonstrated discoloration of the black plastic casing of flexible endoscopes, and irritation of skin, eyes, and respiratory tract.8 It emits a strong odor of chlorine and should be stored in sealed containers and handled in well-ventilated areas.8

**DISINFECTANTS**

Antiseptics are intended for use on living tissue, whereas disinfectants are intended for use on inanimate objects and can harm tissue9 (Table 10-5). An agent can be an antiseptic at low concentrations and a disinfectant at higher concentrations.8

**Aldehydes**

Because heat and moisture are damaging to certain instruments, such as endoscopes, arthroscopes, and laparoscopes, cold disinfection with glutaraldehyde, a dialdehyde (Cidex, Johnson and Johnson Medical, Inc, Arlington, Tex; Omnicide 28, Baxter Healthcare Corp, Deerfield, Ill; Abcocide, Abco Dealers, Inc, LaVergne, Tenn), can be used for these items.7 Olympus, Pentax, and Fujinon list glutaraldehyde as compatible with their endoscopes,8 but manufacturer recommendations need to be closely followed for all such instruments. Although glutaraldehyde is effective against a wide range of susceptible organisms (see Table 10-5),22 Cidex is now classified as a disinfectant by the manufacturer, rather than as a sterilant, and therefore its use on arthroscopic and laparoscopy instruments is questionable.

STERILIZATION AND ANTISEPTICS

PAA sterilization would be the best choice to sterilize these items, as discussed earlier. The antimicrobial activity of glutaraldehyde is greatly enhanced in alkaline solutions, although high pH hastens its polymerization and therefore limits its shelf life. To overcome this problem, glutaraldehyde is supplied as an acidic colorless solution that is activated at the time of use by adding an “activator” that converts it to a green (Cidex, Abcocide) or blue (Omnicide) alkaline solution with a sharp odor.

Repeated use of an activated solution or placing damp instruments into the solution can dilute it to less than the effective concentration. Solutions should be reused only when the minimum effective concentration, as determined by the appropriate test strip, is assured, and when the pH and temperature are correct (Table 10-6). Solutions should be discarded after the specified reuse period has elapsed, even if the appropriate conditions have been met.

Antimicrobial activity of Cidex increases with increased temperature and decreases with organic matter. Therefore, presterilization cleaning and drying are important, and an enzyme-based presoak detergent can be used. Instruments soaked in glutaraldehyde must be thoroughly rinsed with sterile water before they touch tissue, and gloves must always be worn when removing items from glutaraldehyde baths.

The potential hazards of glutaraldehyde for staff are considerable. Toxicity has been suspected in 35% of endoscopy units, with harmful or potentially harmful problems in 63% of these. Direct contact with glutaraldehyde is irritating to skin and other tissues, and repeated exposure can result in sensitization and allergic contact dermatitis. Vapor may cause stinging sensations in the eye, excess tear production, redness of the conjunctiva, a stinging sensation in the nose and throat, nasal discharge, coughing, symptoms of bronchitis, and headache. Glutaraldehyde is not ideal for chemical disinfection of instruments that are hinged, corroded, or have deep or narrow crevices and it should not be used for critical, single-use devices, such as catheters. Prolonged use of glutaraldehyde can corrode metals and some plastics.

Orthophthalaldehyde (OPA; Cidex OPA, Johnson & Johnson’s Advanced Sterilization Products) is a high-level disinfectant that contains 0.55% 1,2-benzenedicarboxaldehyde. OPA completely destroys all common bacteria in 5 minutes of exposure, does not produce noxious fumes, does not require activation, and is stable at a wide pH range (3 to 9). Exposure to OPA vapors may be irritating to the respiratory tract and eyes, and it can stain linens, clothing, skin, instruments, and automatic cleaning devices.

Succindialdehyde with dimethoxytetrahydrofuran and anticorrosion components (Gigasept FF, Schülke & Mayr UK, Ltd, Meadowhall, Sheffield, UK) is recommended for flexible endoscopes and ultrasonic probes by well-known manufacturers (e.g., Fujinon, Olympus, Hewlett Packard, Acuson, Toshiba). It is a broad-spectrum cold-sterilizing or disinfecting solution with excellent material compatibility and a pH of approximately 6.5. It does not require activation additives and might be preferable when avoiding formaldehyde or glutaraldehyde products is desired.

ANTISEPTICS
Alcohols
Alcohols are commonly used in veterinary medicine, but they are effective only against vegetative bacteria (see Table 10-5). They have a mild defatting effect but they are activated by a variety of organic debris and have no residual activity after evaporation. Alcohols have higher and more rapid kill rate than chlorhexidine, and third best is povidone-iodine. The bactericidal efficacy of 1-propanol

Sterilant conditions apply to surgical instruments and devices that penetrate skin or are used in sterile tissues; the longer times are required for spores. High-level disinfectants are used for semicritical devices that do not penetrate sterile tissues (endoscopes, anesthesia equipment). Intermediate-level disinfectants are used for noncritical devices that contact skin surface only. Recommendations for other glutaraldehyde preparations may vary—the manufacturer’s advice should be followed.

can be regarded as superior to that of 2-propanol, and third best is ethanol.27

Either alcohol or sterile saline can be used to rinse the surgical scrub solution from the surgery site. Alcohol does not inactivate chlorhexidine gluconate in vitro and has no significant effect on its protein-binding property in vivo.26 However, isopropyl alcohol rinse can reduce the residual antimicrobial activity of chlorhexidine28,29 and can inactivate hexachlorophene-based preparations (e.g., PlisoFlex).3 Isopropyl alcohol potentiates the antimicrobial efficacy of povidone-iodine by increasing the release of free iodine, so it should be used as a rinse after this surgical scrub.30,31

**Chlorhexidine**

Chlorhexidine diacetate (2%; Nolvasan Solution and Surgical Scrub, Fort Dodge Laboratories, Inc, Fort Dodge, Iowa) and chlorhexidine gluconate (4%; Hibiclens, Stuart Pharmaceuticals, Division of ICI America, Inc, Wilmington, Del) have a rapid onset of action and a persistent effect but variable and inconsistent action against viruses and fungi (see Table 10-5). Chlorhexidine binds to protein of the stratum corneum, forming a persistent residue that can kill bacteria emerging from sebaceous glands, sweat glands, and hair follicles during surgery.33 A recently approved antiseptic for preoperative skin preparation, 2% chlorhexidine gluconate plus 70% isopropyl alcohol (ChloraPrep, Medi-Flex, Inc, Leawood, Kan), provided significantly more persistent antimicrobial activity on abdominal sites at 24 hours than either of the components used separately.34

Chlorhexidine has low toxicity as a skin scrub or as an aqueous solution for wound disinfection, oral lavage, and mucous membranes of the urinary tract.35 Although it can be toxic to fibroblasts in vitro, in vivo lavage with dilute chlorhexidine (0.05%) is not harmful to wound healing.36 However, the least known bactericidal concentration (0.05%) of chlorhexidine diacetate causes synovial ulceration, inflammation, and fibrin accumulation in the tarsocrural joints of horses.35 Chlorhexidine (0.0005%) potentiated with 3.2 mM EDTA and 0.05 mM Tris buffer (hydroxy-methylaminomethylamine) is 90% lethal to Escherichia coli, Staphylococcus aureus, and Streptococcus zooepidemicus and is not harmful to the synovium or articular cartilage of the tarsocrural joints of ponies.36 Chlorhexidine (0.02%), like 1% povidone-iodine, promotes intra-abdominal adhesion formation and therefore should not be used for peritoneal lavage.37

**Iodine Compounds**

Inorganic or elemental iodine has a very broad antimicrobial spectrum compared with other agents (see Table 10-5) and a very short kill time at low concentrations, and organisms do not develop resistance to it.38 Its undesirable characteristics are odor, tissue irritation, staining, radiopacity, and corrosiveness.38 Iodophors are complexes of elemental iodine with a carrier, such as polyvinylpyrrolidone (PVP), which forms povidone-iodine (PVP-I); Betadine surgical scrub, Purdue Frederick Co, Norwalk, Conn. The complex retains the bactericidal activity of iodine, while reducing tissue irritation and staining. Povidone-iodine is usually supplied as a 10% solution with approximately 1% available iodine, which is not equivalent to free iodine but must be converted to free iodine to become bactericidal.38 However, iodine is so tightly bound to PVP that the standard 10% solution contains as little as 0.8 part per million of free iodine.38 This concentration may not be sufficient to kill bacteria, especially as some free iodine is readily neutralized by protein and by conversion to iodide in vivo.38 However, dilution of the 10% solution of povidone-iodine liberates more free iodine than is present in the undiluted solution—thus the diluted solution is more bactericidal.38 Contamination of 10% povidone-iodine solution by bacteria has been reported, apparently because it liberates an insufficient amount of free iodine at this concentration.38 At least 2 minutes of scrubbing is required to release free iodine from povidone-iodine.39 Addition of detergents, as in surgical scrubs, further reduces the release of iodine.39

Before application of iodophor compounds, hair should be removed and the skin well cleaned to remove organic debris that can reduce the bactericidal activity of the iodophor. However, when arthrocentesis sites in the midcarpal joint and the distal interphalangeal joint region of horses were not clipped of hair, a 5-minute surgical scrub with povidone-iodine followed by a rinse with 70% alcohol was as effective as the same regimen on corresponding clipped sites.40 Although a scrub with povidone-iodine, followed by a 24-hour soak in povidone-iodine solution, could reduce bacterial numbers on the surface of the equine hoof, especially if the superficial layer of the hoof capsule was removed, bacterial populations capable of inducing wound infection still remained.41

The toxicity of iodine-releasing compounds is low, although individual sensitivities can occur and some horses may develop skin wheals about the head and neck (e.g., at the laryngoplasty site). Undiluted povidone-iodine solutions have no effect on numbers of viable bacteria in wounds, and povidone-iodine surgical scrub can potentiate infection and inflammation.39 The practice of lavaging the peritoneal cavity with povidone-iodine has been abandoned because of evidence that even dilute solutions can cause a sterile peritonitis in ponies42 and induce metabolic acidosis.38 Although 0.1% povidone-iodine has been reported to be bactericidal and to have minimal deleterious effects on the equine tarsocrural joint,43 it was ineffective in the treatment of experimental infectious arthritis in horses.44 Concentrations greater than 0.05% in vitro can disrupt neutrophil viability and migration.45

A one-step surgical preparation technique using Dura-Prep Surgical Solution (3M Health Care, St. Paul, Minn) is as effective as a two-step povidone-iodine preparation.30 The antimicrobial properties of the solutions are the result of 70% isopropyl alcohol in an iodophor-polymer complex that forms a water-insoluble film with sustained chemical and physical barrier properties on skin.40 In a study on skin preparation for ventral midline incisions in horses undergoing celiotomy, Dura-Prep was as effective as povidone-iodine and alcohol in reducing colony-forming units up to the time of skin closure, and both methods had comparable rates of incisional drainage.46 However, preparation time was significantly shorter for Dura-Prep than with the routine skin preparation technique.38
iodophor and come in different sizes that make them suitable for equine surgery. After the skin has been prepared with an accepted surgical scrub, it is rinsed with isopropyl alcohol and may need to be dried with a sterile towel to improve adherence.46 In some clinics, the proposed surgery site is shaved with a size 40 blade to improve adherence beyond that achieved by clipping.48 A medical grade adhesive drape can also be used (Medical Adhesive, Hollister, Inc, Libertyville, Ill; EZ Drape Adhesive, Clinipad Corp, Rocky Hill, Conn), but this is not essential. Adherence to smooth flat surfaces, such as the ventral abdomen, may be better than to the irregular contour of a joint. A tight adherence of the drape in areas of complicated contours can be achieved by applying the adhesive drape circumferentially while pressing the excess edges of the drape tightly together behind the limb on the side opposite the surgical site. Care should be taken that small pieces of the drape not be torn off and dragged into joints by arthroscopic instruments, to end up as free-floating objects in the joint cavity.

The value of antimicrobial adhesive drapes is questionable.25 In a study on human patients undergoing hip surgery, bacterial contamination of the wound at the end of surgery was reduced from 15% with conventional preparation to 1.6% by use of an iodophor-impregnated plastic adhesive drape (Ioban).47 In a prospective randomized clinical trial on 1102 patients, isolates of normal skin organisms were less frequent when an iodophor-impregnated plastic incise drape was used in clean and clean contaminated abdominal procedures than when the drape was not used.58 However, no difference was found between wound infection rates for patients on whom the iodophor drape was used compared with those patients on whom it was not used.48,49 Although iodophor skin preparations do not produce a radiopaque artifact on intraoperative radiographs, folds in iodophor-impregnated plastic drapes can produce confusing radiographic images.

Chlorhexidine versus Povidone-Iodine

In tests with E. coli and S. aureus on canine skin, 2% chlorhexidine diacetate was superior to hexachlorophene and povidone-iodine in rapid removal of bacteria and in residual activity.50 In another study, chlorhexidine and povidone-iodine were effective in reducing bacteria from surgeon’s hands, but the apparently greater residual effect of chlorhexidine (120 minutes) was not statistically significant.51 Such a residual effect could be of value during long surgical procedures, in which rates of glove puncture could be as high as 17% and many perforations are unnoticed by the surgeon.52 In one study, 4% chlorhexidine gluconate was found to be superior, on the basis of efficacy and prolonged effects, to 7.5% povidone-iodine throughout a 3-hour period after hand antisepsis.53 Compared with iodine preparations, chlorhexidine preparations are less susceptible to inactivation by organic debris.54 Although chlorhexidine’s wider range of antimicrobial activity, longer residual action, minimal inhibition by organic material, and greater tolerance by skin would render it superior to povidone-iodine, both agents perform comparably in the surgical setting.54 In a prospective randomized study of 886 patients, there were significantly fewer wound infections with chlorhexidine preparations for surgical hand washing and patient skin preparation than with povidone-iodine (hand washing and skin preparation) in operations on the biliary tract and in “clean” nonabdominal operations; however, there were no significant differences in a number of other types of surgery.54 The authors concluded that “on the evidence of this study, there is no overwhelming case for using one compound rather than the other as an all-purpose preparation and scrub.”54

Povidone-iodine and 4% chlorhexidine gluconate scrubs rinsed with 70% isopropyl alcohol decreased skin microflora in cattle and had similar frequencies of surgical wound infection.55 Colony-forming unit counts were lower with chlorhexidine and alcohol immediately after scrubbing, but there was no difference in residual effect between the two scrubs.54 Povidone-iodine solutions are inferior to chlorhexidine for wound lavage.56 However, chlorhexidine is more expensive than povidone-iodine.57 Because of concerns about inadequate release of free iodine from povidone-iodine, some consider it to be inferior for skin preparation.58

Phenols

Phenol, cresol, and other coal tar derivates, such as hexachlorophene (PHisoHex; see Table 10-5), are generally considered to be inferior to chlorhexidine and povidone-iodine.9,26 Hexachlorophene has a relatively slow onset of action but a prolonged residual activity, and it is not adversely affected by organic materials. Hexachlorophene-based preparations are inactivated by alcohol.9,26 Use was largely curtailed after hexachlorophene was shown to be neurotoxic at levels obtained with dermal exposure.57

Quaternary Ammonium Compounds

Quaternary ammonium compounds, such as benzalkonium chloride, are cationic surfactants that dissolve lipids in bacterial cell walls and membranes.58 Drawbacks to the group are ineffectiveness against viruses, spores, and fungi, formation of residue layers, and inactivation by common organic debris and soaps.8

Miscellaneous

Hydrogen peroxide is used to clean severely contaminated wounds, but it is a poor antiseptic and is mainly effective against spores, and concentrations lower than 3% are damaging to tissues.59 Chloroxylenol, or parachlorometaxylenol, a synthetic halogen-substituted phenol derivative, and triclosan, a diphenyl ether, do not appear to offer any advantages over the more commonly used antiseptics in veterinary medicine.26,52,60

Current trends in surgical hand disinfection have evolved very rapidly in the last several years and now include alcohol-based and quaternary ammonium compounds using brushless techniques. For a complete discussion on these newer products and techniques, see under “Surgeon’s Skin” in Chapter 11.

CHAPTER 11
Preparation of the Surgical Patient, the Surgery Facility, and the Operating Team
John A. Stick

Having the capacity for sound clinical judgment is the ultimate characteristic of the mature veterinary surgeon. To attain this capacity, the surgeon needs to be able to provide an accurate assessment of operative risk. This can be done only if there is thorough preparation of the surgical patient combined with knowledge of the primary problem, experience, and an open mind.

ASSESSMENT OF OPERATIVE RISK
When determining operative risk, each surgeon must consider the relative rewards and risks in treating a specific illness.1 The surgical risks encompass not only the odds of surviving surgery but also the long-term prognosis, the potential for complications, and the patient’s use and quality of life.2 Basic factors affecting operative risk include age, overall physical status, elective versus emergency operation, physiologic extent of the procedure, number of associated illnesses, and projected surgery time. Although the surgeon can informally consider all this information and make a guess as to the surgical risks based on experience in similar cases, formal assessment schemes are useful. The formal determination of surgical risk can be considered to have two main components: the primary disorder and the general health of the patient.

Primary Disease
Primary diseases with a tendency to progress rapidly and involve other body systems are associated with more risks than those that progress slowly and do not affect the patient’s systemic health. The procedure’s invasiveness and potential for complications are also considered in risk assessment.

Complications and the risk of death increase with the duration of surgery. The risk of surgery also varies with the system involved. For example, diseases involving the gastrointestinal tract have a tendency to cause shock and sepsis early in their course. Elective orthopedic surgery has a much lower associated risk than nonelective general surgeries and major trauma. When emergency surgery is necessary, the surgical risk increases. When a disorder is fatal without surgery but has the potential for a surgical cure, surgery is likely to be recommended despite a high surgical risk.

General Health Assessment
Surgery and anesthesia are never without risks, and unexpected complications can occur even in the healthiest patient undergoing a minor procedure. However, the risks are increased by a variety of conditions. Risk is increased in the very young and the very old. Neonatal animals are predisposed to hypothermia, hypoglycemia, and infection. Morbidity and mortality increase with age in human and veterinary surgical patients.2

The effects of concurrent disease on an animal’s general health are important determinants of surgical risk. Animals with normal physical findings and no history of cardiovascular, respiratory, renal, or liver disorders have a relatively low surgical risk. Additionally, the preoperative nutritional status is an important determinant of surgical risk (see Chapter 6). Cachectic animals may have delayed wound healing and a higher incidence of postsurgical wound infection and susceptibility to multiple organ disorders.

The importance of establishing the physical status cannot be overstated. The American Society of Anesthesiologists has created a classification system for human patients based on evaluation of their physical status, and the rankings can be used to determine surgical risk (Table 11-1). In humans, physical status was second only to albumin level in its

Primary Disease

Complications and the risk of death increase with the duration of surgery. The risk of surgery also varies with the system involved. For example, diseases involving the gastrointestinal tract have a tendency to cause shock and sepsis early in their course. Elective orthopedic surgery has a much lower associated risk than nonelective general surgeries and major trauma. When emergency surgery is necessary, the surgical risk increases. When a disorder is fatal without surgery but has the potential for a surgical cure, surgery is likely to be recommended despite a high surgical risk.

General Health Assessment
Surgery and anesthesia are never without risks, and unexpected complications can occur even in the healthiest patient undergoing a minor procedure. However, the risks are increased by a variety of conditions. Risk is increased in the very young and the very old. Neonatal animals are predisposed to hypothermia, hypoglycemia, and infection. Morbidity and mortality increase with age in human and veterinary surgical patients.

The effects of concurrent disease on an animal’s general health are important determinants of surgical risk. Animals with normal physical findings and no history of cardiovascular, respiratory, renal, or liver disorders have a relatively low surgical risk. Additionally, the preoperative nutritional status is an important determinant of surgical risk (see Chapter 6). Cachectic animals may have delayed wound healing and a higher incidence of postsurgical wound infection and susceptibility to multiple organ disorders.

The importance of establishing the physical status cannot be overstated. The American Society of Anesthesiologists has created a classification system for human patients based on evaluation of their physical status, and the rankings can be used to determine surgical risk (Table 11-1). In humans, physical status was second only to albumin level in its
accuracy in predicting survival and postoperative complications.\(^3\) Similar findings were observed in high-risk canine surgical patients: 92% of canine patients assigned to American Society of Anesthesiologists class II survived, compared with 73% in class III and 38% in class IV.\(^5\)

**Personal Relationships**

A bond of communication, cemented with personal responsibility, is established between the surgeon and the client (usually the animal owner), whenever a surgical procedure is being considered. The confidence of the well-informed client is based on a true understanding of the situation, which allows the client to participate in judgments regarding operative risks, outcomes, the process of postoperative recovery, and financial implications. Legal action is rare when a careful effort has been made by the veterinarian to achieve such understanding before an operation.

Veterinary surgeons should also appreciate the importance of an effective relationship with the referring veterinarian. In many situations, patients are referred to surgeons by veterinarians with valuable skills and expertise. It is important to understand the wishes and views of the referring veterinarian. Differences in judgment must be discussed. Both the surgeon and the referring veterinarian should be aware of the expected course of treatment and the extent of the referring veterinarian’s participation in postoperative care. This avoids communication errors and contradictory efforts.

True informed consent is attained when there is a full and frank discussion with the client in the presence of an appropriate professional witness.\(^1\) The surgeon should record a summary of this encounter in the hospital chart. The surgeon should also record why the operation is needed, the operative risks, and the problems anticipated intraoperatively and postoperatively. When a condition is expected to have a clinically significant course beyond the duration of the early follow-up period, the client should be told how much continuing commitment will be needed.

**PREPARATION OF THE SURGICAL PATIENT**

**History**

The first step in assessment of the patient is interviewing the owner to determine the animal’s medical history, its overall health, and the impact of the presenting complaint.\(^2\) At this time, the surgeon should determine the owner’s wishes and expectations.

The patient’s signalment should be reviewed to determine the potential for problems related to age, breed, and sex.
Questions about the animal’s general health and environment can contribute to making the diagnosis. The animal’s intended use and the owner’s expectations of its future performance are explored to gauge the future satisfaction of the owner with the proposed procedure. Past medical problems should be discussed, because they may influence the outcome.

Physical Examination
Despite a surgeon’s natural tendency to focus on the presenting problem, a thorough physical examination should include an assessment of each system. A general physical examination determines the need for in-depth assessment and preoperative stabilization. It is this examination that is most likely to identify risk factors affecting surgical outcome. The animal should first be examined for general demeanor, nutritional status, and gait. Temperature, pulse, and respiration rate are noted as the respiratory and cardiovascular systems are emphasized.

Finally, the affected area and related systems are evaluated. A physical status rank, based on the American Society of Anesthesiologists classification system (see Table 11-1), should be assigned. This will allow a more accurate determination of what supplemental testing should be performed.

Supplemental Testing
Laboratory testing is not a substitute for the thorough examination, and all abnormal findings in the laboratory data should be interpreted in light of the initial physical findings. When abnormalities in the function of organs (e.g., the heart, kidneys, and respiratory system) are detected, testing may be expanded to include chest radiography, urinalysis, and biochemical profile. However, although preoperative tests that screen for clinically silent disease will not replace the physical examination, some basic laboratory data are recommended for use with the American Society of Anesthesiologists classification system for physical status (see Table 11-1).

Physiologic Preparation
In preparation for elective surgery, steps should be taken to correct physiologic deprivations. Procedures in chronically anemic patients should be delayed until the anemia can be corrected. If fluid deficits exist, plasma or fluids should be administered in appropriate volume, concentration, and composition (see Chapter 3). Although not all volume and concentration deficits need to be corrected before the surgery, a significant fraction of the total deficit should be replaced to enhance the safety of the anesthesia, even in emergency patients. Nutritional replenishment supplementation should be provided for a patient that awaits an elective operation if deficits are obvious.

Infection rates of surgical wounds in horses are higher than those seen in people and dogs. Overall infection rate for equine orthopedic surgeries has been reported to be 10%, compared with 4.7% in people, and 5.1% in dogs and cats.6-9 Infection rates for abdominal surgery in horses have been reported to be 25.4% and 30%.7,8 Therefore, a primary consideration in preparing the patient is antibiotic prophylaxis. Because equine patients do not live in particularly clean environments, antimicrobial drugs are frequently administered prophylactically even for elective orthopedic surgeries. For additional information on surgical infections and management of sepsis, see Chapters 7, 10, and 88.

Skin Preparation
The patient is the primary source of pathogens involved in surgical wound infections and, therefore, should be groomed before surgery, or even bathed if the hair coat contains a lot of organic material, and the tail should be wrapped. Preparation of the surgical site should include hair removal and cleansing to remove dirt and oil and to reduce resident skin flora. It has been suggested that using a no. 40 clipper blade to clip over the entire surgical area, followed by scrubbing, applying antiseptic solution, and wrapping the limb with a sterile bandage overnight, reduces the chance of contamination in orthopedic cases. However, clipper blades used repeatedly without sterilization have high levels of bacterial contamination and, therefore, are a potential source of infection.10,11 Sterilization of clipper blades between uses has been shown to decrease bacterial counts. A study in humans revealed that using razors for the close removal of hair caused significant injury to the skin and increased bacterial colonization by altering wound defense mechanisms and delaying healing.11 Therefore, if the surgical site is to be shaved, it should be done immediately before surgery and not the night before.

Clipping should be performed whenever possible outside of the surgical theatre, as should the initial skin preparations. The limb from the elbow and stifle distad should be clipped circumferentially in the region of the surgery site. Additionally, the hair should be clipped 10 cm further proximad and distad relative to the intended surgery site to facilitate appropriate skin preparation and draping. If possible, only the final skin preparation should be performed in the surgical theatre to avoid dust, dander, and exfoliated skin cells from contaminating the environment.

The optimal scrub time for maximal reduction of skin flora and lowest wound infection rates has not been determined for the horse. A 5% povidone-iodine solution or 4% chlorhexidine diacetate used for 10 minutes, alternating with an alcohol rinse, is currently recommended, and other scrub solutions are available (see Chapter 10). Surgical scrubs are applied to an area starting at the expected surgical incision and moving outward in expanding concentric circles, extending the outer margins of the clipped area (Fig. 11-1). This maneuver is repeated, alternating rinse solutions with the antiseptic until the sponges are free of visible soiling. Then a final application of the disinfectant is applied and left in place (Fig. 11-2). When distal limbs are scrubbed, the entire circumference of the limb is prepared, applying the scrub at the proposed surgical site and expanding distad and proximad, as just described.
Draping the Surgical Field

Ideally, barrier materials prevent the movement of debris and bacteria from nonsterile areas onto the surgical field for the duration of surgery. They should be easy to sterilize and economical, and they should retain their barrier properties if they are washed, sterilized, and reused. Woven fabrics that are intended for reuse consist of interlacing fibers that cross at right angles. The number of threads per square inch reflects the tightness of the weave, and the higher the number is, the tighter the weave and the more effective the barrier.

Reusable woven fabrics fall into two categories: cotton muslin with 140 threads per square inch, and pima cotton with tightly twisted fibers woven into 270 threads per square inch. The cotton muslin is not a good barrier. It instantly allows passage of bacteria when wet (termed strikethrough), and dry penetration of bacteria may also occur because its pore size is 50 to 100 µm, which is large enough to allow bacteria (5 to 12 µm) to pass through. On the other hand, pima cotton has a weave tight enough to prevent penetration by skin squames, but it readily allows penetration of bacteria when wet. A chemical treatment process, Quarpel, makes cotton fabric water resistant by providing a fluorochemical finish in combination with pyridinium or a melamine hydrophobe. This process renders pima cotton an effective barrier for up to 75 washings. It is necessary to record the number of washings each piece of fabric undergoes to ensure that it is replaced before the barrier properties become ineffective.

A disadvantage of reusable woven fabrics is that they can sustain tears or punctures from towel clamps (therefore, only nonpenetrating clamps should be used at the surgical site) and needles, which destroy their barrier function. Although holes can be repaired with vulcanized fabric patches, these patches generally resist autoclave steam penetration, so this material becomes less than an ideal barrier.

Disposable materials are made from cellulose, wood pulp, polyesters, or synthetic polymer fibers, formed into sheets and bonded together. The barrier properties of the various nonwoven materials differ a great deal. Polymeric ingredients in these barriers tend to be more impermeable, but only those with a reinforced polyethylene or plastic film prevent moist and dry penetration at pressure points. Although disposable drapes result in lower particle counts in the operating room (because of the lack of lint from cotton), the air bacterial counts are similar to those of reusable drapes. However, they are reported to decrease the number of bacteria isolated from the surgical wound by up to 90% compared with the cloth draping systems, and surgical wound infection rates decrease by a factor of up to 21/2. Because the difference between the two materials appears to be small, the choice is often based on economics and convenience; however, when large volumes of liquids are
expected in the surgery (e.g., in colic and arthroscopic surgery), nonwoven disposable materials appear to be the material of choice for barrier drapes.

Before moving the patient into the operating theatre, the patient should be covered with a clean drape and its feet should be covered with plastic bags or other water-impermeable coverings to prevent contamination from the foot and distal limbs. After the patient is positioned in the room and the final preparation of the surgery site is completed, draping begins at the surgical site and moves outward.

Drapes are applied to all visible surfaces of the patient, providing a barrier to aerosolization of debris from nonsurgically prepared portions of the animal’s skin. When applying drapes, the surgeon’s gloved hands are positioned on the side of the drape away from the animal’s skin and are protected by curling the outer surface of the drape over the hands (Fig. 11-3). The portion of the drape that is to be adjacent to the incision is positioned first and then moved peripherally to the desired location, never the reverse. It is desirable to drape closely, leaving no unnecessary skin exposed. Drapes are generally positioned in a four-quadrant method, with separate drapes in each quadrant, leaving a rectangular area of the surgical field exposed. It is recommended that this process be repeated to double drape the area immediately adjacent to the surgical site.

Self-adhering drapes are helpful when larger areas need to be exposed for topographic orientation and palpation. The goal of multiple layers of draping is to build a waterproof barrier that extends to cover the entire patient. When the distal limb is draped, the quadrant method may be used. However, providing access to the entire circumference of the limb is often preferred, especially during orthopedic procedures. In such a case, the foot is often covered with a rubber glove, and circumferential draping is applied, first by wrapping around the foot and then around the proximal limb. Next, a self-adhering sterile drape (Ioban 2, 3M Health Care, St. Paul, Minn) is applied over the foot and the half-sheet that has been applied to the proximal limb. Then an extremity sheet with a fenestration is passed over the foot and secured around the limb proximal to the surgery site (Fig. 11-4).

Because there is a risk of contamination during draping, it is best to practice double gloving for the act of draping, removing the outer gloves immediately thereafter.

The surgical field is defined by areas above and level with the surgical wound (Fig. 11-5). Even if draped, areas below the level of the wound should be considered contaminated and not part of the surgical field.

**THE SURGICAL FACILITY**

With the increasing sophistication of surgical techniques and instrumentation available today, surgeries outside a proper surgical facility are becoming less common. If the procedure to be performed is expected to be lengthy, complicated, or sophisticated, use of a designated operating...
room is the standard of care. Surgical operating facilities should allow for separate induction, preparation, and recovery rooms and for a minimum of two surgical suites so that clean procedures can be performed in one surgical suite dedicated to strict aseptic surgical procedures, and the other suite can be used for contaminated or infected procedures (Fig. 11-6). The surgery suite should be convenient to the work and have adequate room for the patient, people, and equipment. The average size of an equine operating room should measure 8 m² (25 square feet). Separate induction and recovery rooms should be available for each surgical suite. Floors and walls should be surfaced so that cleaning is efficient, and drains should be placed so that water does not pool anywhere in the surgical suite after cleaning. Drains should be of sufficient diameter to remove the material and should contain a flushing system so that they do not harbor potentially dangerous mixtures of blood, feces, and bacteria. One-way traffic should be maintained from patient preparation area to the operating suite and then to the recovery room. After induction of anesthesia, the patient should be properly positioned on the surgery table and prepared for aseptic surgery, and then the table with the horse should be transported into the surgery suite. The suite should not be a high-traffic area, and proper surgical attire, including caps, boots, mask, and surgical caps, should be worn when in the operating theater.

A room temperature of approximately 20°C (70°F) with a relative humidity of 50% provides a comfortable environment. Air within the operating room should be under mild positive pressure, so that when the doors open, air flows out of the room rather than into it. A minimum of 25 air exchanges per hour is recommended if the air is recirculated, and 15 air changes per hour if the air is exhausted to the outside. In selected human surgery suites, especially those used for joint replacement, laminar air filtering systems are installed to reduce the number of airborne microorganisms in the surgery suite. The filtering system measures about 3×3 m (Fig. 11-7). The air is directed in a vertical flow of 0.5 m/sec initially through a rough, then through a fine, and ultimately through a high-efficiency particulate air (HEPA) filter. The ultra-clean air reaches the surgical field and is directed around the patient to the floor. From there it is aspirated into exhaust outlets located all around the walls at the ceiling. The air is recirculated through the filtering system. Ideally, the outline of the filtering system is marked on the surgery room floor, which facilitates the positioning of the surgery site, the instrument tables, and surgeons within the field (Fig. 11-8). Such ultra-clean filtering systems

**Figure 11-6.** Suggested layout for an equine surgical facility. Separate rooms are provided for clean procedures and for contaminated or infected procedures, and a central station supplies both suites. AE, anesthesia equipment; CW, client waiting room; I, induction stalls; LB, laboratory bench; M, men’s dressing area; NS, nurse’s station; OR, operating rooms; PP, pack preparation and storage; R, recovery stalls; SR, scrub room; W, women’s dressing area.
Figure 11-7. Schematic drawing of a laminar air filter system. The surgical site, the surgeons, and the instrument tables must be situated in the field of filtration. a: Blower to force filtered air through the pores in ceiling. b: Laminar air filter in the ceiling (frequently illuminated). c: Laminar air stream gently falling towards the floor. All objects within the field are surrounded by this air. d: Once at or near the floor, the air is directed toward the periphery and some of it is lost through doors and other openings. The rest is gently pulled up toward a filter system mounted along the walls in the ceiling. e: After being extensively filtered and mixed with clean air from outside, the air is directed through the blower (f) again and reentered into the cycle.

Figure 11-8. View into the aseptic surgery suite of the Equine Hospital, University of Zurich. a: The laminar air filter is illuminated. b: The grey area marked on the floor delineates the extent of the filter field. The surgery site, the surgeons, and the instrument tables need to be located within this field during surgery. (A mobile Haico Surgery table is shown in the room). c: A movable video camera (left) is mounted on the ceiling together with a video screen.
in the room, the amount of uncovered skin area, and the amount of talking. Bacterial levels in excess of 400 per cubic foot may be seen in a busy operating theatre. Therefore, barrier apparel is worn to minimize these numbers and their effect on surgical wound rate.

THE OPERATING TEAM

Scrub Attire

The operating team consists of the people performing the surgery and administering the anesthesia, nonscrubbed assistants, and observers within the operating room. All individuals, regardless of their role in the surgery, contribute to operating room contamination and potential infection of the wound. Therefore, scrub suits, caps, masks, sweat bands, shoe covers, gowns, and gloves are worn to prevent shed particulates and microorganisms from reaching the surgery site.

Scrub suits usually consist of separate pants and shirts and should be clean, comfortable, and dedicated to the operating room (Fig. 11-9). Many blended cotton materials are available for this purpose. Although the design is relatively standard, sizing should accomplish covering the surgeon effectively from neck to ankle while leaving the arms exposed. The bottom of the scrub shirt should be tucked into the pants to prevent shedding of hair, skin cells, and bacteria between the top and the pants. Long-sleeved cuffed jumpsuits for those not needing to gown and glove for the procedure are also quite useful, as they provide a barrier against shedding of skin debris and microorganisms. The scrub suit should not be worn outside the surgery without being covered by a clean laboratory coat, and it should be laundered after each case or at least daily. This scrub clothing should be steam sterilized weekly to ensure removal of the microorganisms that can remain after routine laundry cleaning. Alternatively, bleach can be added to the laundry cycle to reduce the number of bacteria.

Air in an operating room contains approximately 250,000 particles (bacteria, lint, and skin squames) and 11 to 13 bacteria per cubic foot. These particles and bacteria increase with the number of people and level of activity in the room. The door should be wide enough to allow the surgery table with the horse and other large equipment such as the digital-capture C-arm and radiography machines to pass through easily. Electrical outlets should be located waist high or suspended from the ceiling so they do not become wet during cleaning of the room. Ideally, several locations for hooking up the anesthetic gases and the exhaust pipes of the anesthetic machine should be available. Also, devices should be placed in the wall to allow the application of traction pulleys for the reduction of fractures. Some provision should be made for emergency lighting, either by battery units or with an emergency generator that starts automatically when needed. At least one surgery light in each room should be wired to the emergency system. All cabinets should be recessed into the wall so that the floor can be adequately cleaned after each surgery. Viewing windows are desirable in operating rooms. This is done not only for direct viewing from a doctor or nurse’s station but also so the public can view surgeries from an outside hall. Another option is the installation of a closed-circuit video camera system, which can be operated by the owners or students from an observation room distant from the surgery facility.
Head Covers

Human hair is a major source of bacteria. Because the uncovered hair of the surgeon, who stands over the incision, is frequently a major source of surgical wound contamination, head covers are worn to reduce the shedding of hair and bacteria. All people in the operating room should wear head covers—caps, hoods, or bouffants (Fig. 11-10). These are available in reusable cloth and disposable nonwoven material. The covers should cover all the hair on the head. The reusable head covers should be washed after every procedure (up to a total of 75 times and then, like the reusable drapes, discarded).

Gowns

Gowns provide an aseptic barrier between the skin of the operating team and the patient. The gown should be water resistant as well as comfortable and breathable. It should not produce lint. Gowns are packaged individually and folded so the interior back region is outermost, allowing this area to be handled without contaminating the gown’s exterior surface. Once donned, the sterile surgical field extends only above the waist (see Fig. 11-5).

Gowns, like the draping materials, can be made of either reusable woven fabric or nonwoven disposable material. The most effective barrier gown contains some type of polyester or plastic film over a breathable material. Preventing strike-through when becoming wet is an attribute that is almost mandatory for surgical gowns. Gortex gowns with double-layered barriers in the elbows, chest, and abdominal areas have become popular because they are comfortable and meet the necessary criteria. Gortex is a barrier material consisting of an expanded film of polytetrafluoroethylene between two layers of fabric with a maximal pore size of 0.2 mm, which resists strikethrough by water, and bacteria. It allows evaporation of perspiration, which increases comfort for the surgeon. Gortex fabrics are more durable than Quarpel-treated pima cotton and will retain barrier quality characteristics for up to 100 washings.

Gloves

Surgical gloves are made of natural rubber latex and are provided in a sterile, single-use package. Gloves should fit tightly, because gloves that are loose will impair dexterity, but they should not be so tight that the surgeon’s fingers lose sensitivity. Modified cornstarch is preapplied to most gloves for easier application, and therefore the outside of the gloves should be rinsed before patient contact. Cornstarch is referred to as "absorbable powder." Magnesium silicate (talcum) powder is no longer used in powdered gloves because it potentiates latex allergies and causes granulomas in patients even when gloves are thoroughly rinsed. However, even absorbable powdered gloves contribute to natural rubber latex allergies (which cause contact dermatitis), and the powder acts as an airborne carrier of natural latex proteins (which can cause respiratory allergies). Therefore, most surgical gloves are treated with multiple washings to reduce the latex proteins. If allergies develop to latex, powderless latex gloves are available, which are chlorinated during manufacturing to decrease their tackiness. (However, these gloves do not store well, and inventory should be monitored to avoid use of these gloves beyond the expiration dates as failure becomes common.) Alternatively, vinyl gloves are available to eliminate this problem, although their performance is less desirable (i.e., dexterity is reduced).

The accepted industry standard for surgical gloves is that 1.5% contain punctures before use. One study found that 2.7% of latex and 4.1% of vinyl gloves leak when filled with
water. By the end of surgery, up to 31% of gloves have perforations, and when double gloves are worn, 16% to 67% of the outer gloves and 8% to 30% of the inner gloves contain perforations. Holes are most common on the thumb and index finger of the nondominant hand. Although gloves can be applied using closed or open gloving technique, closed gloving techniques are preferred because the surgeon's skin will not make contact with the outside of the gown cuff. If soiling of the gloves is expected or extra protection is needed during a surgical procedure (i.e., during most orthopedic procedures), many surgeons elect to apply and wear a second pair of gloves. Cuffs of the surgeon's gown should be completely covered, because cuff material is not impervious to water penetration. The use of plastic safety sleeves often helps when the surgeon's hands and arms may be submerged, such as at a colic surgery. Extra-thick gloves are available for orthopedic surgeries, where there is an increased risk of puncturing the gloves from sharp bone spikes and implant materials.

**Face Masks**

Facial coverings are not effective bacterial filters. When properly fitted, they redirect airflow away from the surgical wound and in doing so reduce the potential for surgical wound infection (Fig. 11-11). Despite clinical reports that facial coverings do not reduce surgical site infections, the use of a face mask is considered mandatory during surgery. Tied-on face masks are tied over the head first, the wire on the top of the mask is fitted over the surgeon's nose, and the lower ties are pulled around and tied behind the neck. The mask should fit tightly around the sides of the face and over the tip of the chin. Cup masks with elastic bands provide a better fit and offer less chance of bacterial contamination.

Disposable surgical face masks are recommended over washable gauze because of improved efficiency and comfort. Masks should be worn by all personnel entering the surgery room at any time. Failure to wear masks even when surgery is not in progress promotes contamination of the surgical area. Masks should not be removed and replaced, pushed on the top of head, dangled from the chin, or tucked in a pocket. Each of these common practices risks contamination of scrub clothing with bacteria from inside the mask, which may be transmitted to the patient. The effectiveness of masks and other barriers in a surgery room should probably not be relied on for more than 2 hours. A frequent change of masks, caps, and other apparel is warranted when this time period is exceeded. Bearded surgeons should wear a hood that covers all facial hair in addition to a face mask, which alone is insufficient.

**Foot Covers**

Disposable shoe covers are usually made of light, nonwoven material fabric and sometimes have polypropylene coatings to avoid strikethrough. Shoe covers help keep the surgeon's feet dry and thus more comfortable during surgical procedures, but they are not believed to be useful in reducing the soil brought to the operating room floor in an equine surgery suite, because of the obvious soiling that occurs with this type of patient. Therefore, shoes dedicated to the operating room are a better option for reducing environment contamination; these shoes should never be worn outside the surgery area without shoe covers, which are then removed prior to reentering the surgery suite.

**Surgeon’s Skin**

Surgeon's hands have higher bacterial counts and more pathogenic organisms than the hands of other medical personnel because of increased exposure to scrub solutions (which irritate the skin) and contaminated wounds. The objective of a surgical hand scrub is to remove gross dirt and oil and decrease bacterial counts, and just as importantly to have a prolonged depressant effect on transient and resident microflora of the hands and forearms. Surgical scrub protocols are based either on scrubbing time or on stroke counting. Principles of the scrub procedure are standard. Fingernails are kept short, clean, and free of polish and artificial nails (chipped nail polish and polish worn for more than 4 days foster an increased number of bacteria on the fingernails, even after a surgical hand scrub). All surfaces of the hands and forearms below the elbow are exposed to antiseptic scrub. Special attention is paid to the area under the nails. The ideal scrub time is controversial, but 2 to 5 minutes seems to be safe and effective, depending on the agent used. Ten-minute scrubs are no longer used because they do not result in additional reductions in
bacterial counts (and in one study, counts were increased) and are more irritating to the skin, and 2-minute scrubs result in bacterial count reductions similar to those of longer scrub times. It is currently recommended that brushes or sponges be used for the first scrub of the day, but subsequent scrubs can be brushless.

The residual activity of antisepsis is widely accepted as being useful in the preoperative disinfection of the surgeon’s hands. The residual activity of either chlorhexidine gluconate or alcohol chlorhexidine is reported to be superior to that of povidone-iodine against resistant bacteria. Therefore, for procedures lasting less than 1 hour, povidone-iodine is acceptable, but if the procedure is going to exceed 1 hour, alcohol chlorhexidine or chlorhexidine gluconate is the antiseptic of choice.

The primary objective of surgical hand disinfection is destruction or maximal reduction of the resident flora; the secondary objective is elimination of the transient flora. Surgical hand disinfection with alcohol-based hand rubs, many of which contain emollients, is growing in popularity over surgical hand washes made of an antiseptic-based liquid soap, because the rubs have a rapid and immediate action, do not require water or a scrub brush, are considerably faster than the traditional hand scrubs, and cause less skin damage after repeated use.

One large veterinary clinic in Europe (University of Zurich) uses a combination of three products in sequence. A disinfectant solution, Bactolin (Bode Chemie, Hamburg, Germany), is applied with a soft brush or foam pad as the initial wash. Then the hands are dried, and 10 mL of Sterillium (Bode Chemie) is applied for 3 minutes. Postoperatively, Baktolin Balm (Bode Chemie) is applied for rehydration. Sterillium contains 2-propanol (45%) and 1-propanol (30%), and mecopropion ethyl sulfate (MES), a nonvolatile quaternary ammonium compound with skin-soothing and mild antiperspirant effects. Manufacturer’s claims are exceptionally good skin protection and skin care, even with long-term use, efficacy against a broad range of microorganisms and viruses (bactericidal, fungicidal, tuberculocidal, virus inactivating), and excellent residual effect. The manufacturer also claims that this preparation permits penetration deep into the stratum corneum of the skin, where it forms a defensive barrier against organisms that emerge with perspiration.

Bacterial examination after disinfection was conducted in two ways. The volunteer rubbed the distal phalanges of one hand (randomly selected) for 1 minute in a Petri dish containing 10 mL of tryptic soy broth (TSB) supplemented with neutralizers (immediate effect). The other hand was gloved for 3 hours for the assessment of the sustained effect. After removal of the glove, sampling was done as for the immediate effect. From the sampling fluid, two 1 mL and two 0.1 mL aliquots were seeded, each in two Petri dishes with solidified TSA. A 1:10 dilution of the sampling fluid in TSB was prepared, and two 0.1 mL aliquots of this were seeded as above. Dishes were incubated at 37° C for 24 to 48 hours. For each dilution the mean number of colony-forming units scored in duplicate dishes was calculated. This was multiplied by the dilution factor to obtain the number of colony-forming units per milliliter of sampling liquid. The examination technique described above has confirmed that rubbing the hands with an antiseptic is significantly more effective than scrubbing with brushes. Hand rubbing with 0.2% chlorhexidine and 83% ethanol (Hibisoft, Sumitomo Pharmaceutical Co, Osaka, Japan) suppressed the number of bacteria and prolonged sterilization for more than 3 hours. In a study conducted according to two European standards for bactericidal efficacy, all alcohol-based surgical hand rubs (Sterillium and Softa Man) and the hand washes, chlorhexidine (Hibiscrub), and povidone-iodine (Betadine) fulfilled the requirements of a bacterial suspension test. However, only the hand rubs met the requirements of the in vivo test of efficacy on resident skin flora, and chlorhexidine failed that test. In another study on surgical hand scrubs, Sterillium was superior to Hibiscrub and alcoholic gels in terms of skin tolerance and microbicidal efficacy.

A 1% chlorhexidine gluconate solution and 61% ethyl alcohol with moisturizers (Avagard, 3M Animal Care Products, St. Paul, Minn) is currently in use as a hand cleaner in the United States. Advantages claimed are greater preservation of the skin’s own moisture, pliability and integrity, rapid microbial kill, and activity against a wide range of organisms, including methicillin-resistant Staphylococcus aureus. It has been shown to have residual activity comparable to that of chlorhexidine gluconate alone and greater than that of povidone-iodine. A similar product, 0.5% chlorhexidine gluconate plus 70% isopropanol (Hibisol, Promed, Killorglin, Ireland) has greater residual activity against clinically significant test organisms than chlorhexidine digluconate skin cleanser (Hibiscrub), povidone-iodine surgical scrub (Betadine), or 60% isopropanol.

Despite growing evidence in favor of alcohol-based hand rubs for preoperative preparation, many surgeons remain reluctant to switch from an antiseptic soap to an alcohol-based hand rub. Large-animal surgeons pose a considerable challenge to methods employed in human hospitals, because they so often handle heavily contaminated areas on their patients before surgery. Therefore, thorough prewashing is strongly encouraged before using alcohol-based hand rubs.

Additionally, recently developed microbicide products containing substituted phenolic and quaternary phospholipids have 30-second kill times and are used in 2-minute brushless scrubs (Techni-care, Care-Tech Laboratories, Inc., OTC Pharmaceuticals, St. Louis, Mo). These products are less irritating to the skin and are being used in several hospital applications, even including the direct applications to infected and open wounds. All of these products are recommended to be used with a skin balm after surgery to prevent the surgeon’s skin from drying with multiple uses.

**Staffing the Surgery Area**

A minimum of three persons is recommended to perform equine surgery. A surgeon, an anesthetist, and a dedicated surgical technician form the minimal operating team for most efficient operation and least risk to the patient. The properly trained anesthetist allows the surgeon to concentrate entirely on the surgical procedure and must be able to restrain patients effectively and place catheters, calculate drug doses, and be familiar with various sedative and anesthesia techniques.
anesthetic agents and regimens. The surgical technician becomes an extension of the veterinary surgeon and usually is more adept than the surgeon in the support areas.

An operating room supervisor is important regardless of the size of the facility. The supervisor is responsible for ordering and stocking all supplies, maintaining a surgery log, and recording all controlled substances and their use. The dedicated surgical technician can fill this role. Additionally, a surgical assistant is invaluable, and technicians with the proper basic training skills and attitude can be acceptably competent in a relatively short time with minimal training, rounding out the team to a perfect four.

CHAPTER 12

Surgical Instruments

Jörg A. Auer

Veterinary surgeons have access to all the instruments used by surgeons who operate on humans, and to an increasing number of instruments specially designed for veterinary applications. However, the instruments actually used by a surgeon are determined by a combination of economics, predicted use, specialty considerations, and personal preference. The costs involved in the purchase of instruments are substantial and demand a clear understanding of manufacturing procedures, maintenance, and potential applications during surgery. Surgical instruments are offered by a large number of manufacturers. As they all compete for the same customers, advertisements usually include an attractive purchase price, which can be the result of compromised quality standards during manufacturing. Unfortunately, there are no international standards for instrument quality. As a result, caution must be exercised before purchasing instruments at bargain prices. When costs for replacement of prematurely worn-out instruments are combined with the frustrations encountered during surgery because of poorly functioning equipment, the higher costs of high-quality instruments are justified. On the other hand, some disposable instruments intended for human surgery can be used repeatedly by veterinary surgeons, which reduces costs considerably.

CHAPTER 12

Surgical Instruments
Jörg A. Auer

Veterinary surgeons have access to all the instruments used by surgeons who operate on humans, and to an increasing number of instruments specially designed for veterinary applications. However, the instruments actually used by a surgeon are determined by a combination of economics, predicted use, specialty considerations, and personal preference. The costs involved in the purchase of instruments are substantial and demand a clear understanding of manufacturing procedures, maintenance, and potential applications during surgery. Surgical instruments are offered by a large number of manufacturers. As they all compete for the same customers, advertisements usually include an attractive purchase price, which can be the result of compromised quality standards during manufacturing. Unfortunately, there are no international standards for instrument quality. As a result, caution must be exercised before purchasing instruments at bargain prices. When costs for replacement of prematurely worn-out instruments are combined with the frustrations encountered during surgery because of poorly functioning equipment, the higher costs of high-quality instruments are justified. On the other hand, some disposable instruments intended for human surgery can be used repeatedly by veterinary surgeons, which reduces costs considerably.
MATERIALS

A description of the different compositions of stainless steels used for manufacturing instruments is found in Chapter 9. Here, only some general comments referring to instrument materials are made.

High-quality stainless steel has become the material of choice for most surgical instruments. In its various forms, stainless steel exhibits a number of desirable instrument characteristics, such as hardness, ability to hold an edge, and resistance to wear and corrosion. Variation in the carbon content of the steel results in changes in the handling characteristics of the material to meet special needs. Currently, most stainless steels used for instrument manufacturing contain a high content of carbon. Although high-carbon stainless steel is resistant to wear and allows the instrument to hold its sharp edge, tungsten carbide inserts have been introduced to replace stainless steel cutting and gripping surfaces (Fig. 12-1). These inserts are even harder and more resistant to wear, prolonging the life of the instrument considerably. The bond between these inserts and the body of the instrument represents a potential problem area, because these bonds may loosen through frequent use and sterilization.

The fine edges and working surfaces required for microsurgery have led to the use of titanium alloys for this specialty instrumentation. Titanium alloys can be produced with excellent corrosion resistance and temperature strength. The brittleness of such alloys complicates the manufacturing process and dictates particular care during use and maintenance. Manufacturers’ recommendations for cleaning and sterilization of titanium alloy instruments should be closely followed.

Before the wide availability of low-cost stainless steel, many instruments were manufactured from chrome-plated carbon steel. The chrome plating provided corrosion resistance unavailable with carbon steel alone. Unfortunately, the chrome plating itself is susceptible to early deterioration from frequent rough use and exposure to acidic solutions. Failure of the chrome coating exposes the underlying carbon steel, allowing oxidation and rust formation. Although deteriorated instruments can be refurbished and replated, replacement with higher-quality, longer-lasting stainless steel instruments is more cost effective and is strongly encouraged.

Corrosion resistance can also be improved by the process of passivation. This process uses nitric acid to remove foreign materials from the stainless steel surface, while covering it with a thin coat of chromium oxide. Both actions contribute to corrosion resistance of surgical stainless steel. Polishing the instrument provides a very fine instrument surface, further increasing corrosion resistance.

One popular surface finish for increased corrosion resistance is a dull satin finish. Created by abrasion or sandblasting techniques, the satin finish reduces light reflection and thus eyestrain. A black finish, which serves a similar purpose, is also available. Gold electroplating of instrument handles does little to improve working surfaces but is generally recognized as a symbol of high-quality instrumentation.

GENERAL SURGERY INSTRUMENTS

Hundreds of different instruments are available today, and it is impossible to know them all by name, function, and design. Frequently, similar instruments are modified and manufactured under different names. In this chapter, instruments are discussed in groups according to function, and differences within the groups are mentioned when needed. All basic instruments should be known to all surgeons, which will aid in the selection of the appropriate instrument for a specific procedure and expedite communication during surgery. The parts of a typical surgical instrument are identified in Figure 12-2. Specialty instruments will be covered in subsequent chapters where applicable.

Figure 12-1. A, Mayo-Hegar needle holder with tungsten carbide inserts. B, Metzenbaum surgical scissors with tungsten carbide inserts. (Reprinted with permission from Miltex Instrument Company, Bethpage, NY, 2004.)

Figure 12-2. Top: Labeled parts of a typical surgical instrument. Bottom: End-on view of the ratchet mechanism. The ratchets should be slightly separate when the jaws are closed.
Instruments that fall into more than one category are described only once.

**Scalpels**

**Steel Scalpels**

Scalpels are available with detachable blades, as disposable units with blades attached, and as reusable units with blades attached. In most clinics, the Bard-Parker scalpel handles with different detachable disposable blades are used (Fig. 12-3). The Bard-Parker no. 3 scalpel handle is the most frequently used. Most surgeons prefer the no. 10 blade; the no. 15 blade is a smaller version in a similar shape. The no. 11 blade is frequently used for stab incisions during arthroscopic surgery, and the no. 12 blade is used for periosteal stripping. Two narrow blade handles, Bard-Parker no. 7 and no. 9 (see Fig. 12-3, C, and D), receive the same blades and are more appropriate for delicate work. The Bard-Parker no. 4 handle accepts larger blades (see Fig. 12-3, F). A detachable blade should not be used in joints or deep within heavy connective tissues, where they could break off and be lost from view. The primary advantage of disposable blades is that replacement blades are consistently sharp.

The reusable scalpel with attached blade has a single advantage over the disposable units: the blade will not detach when used in heavy connective tissue, within joints, or in deep tissue planes, where visibility and access for removal are poor. Ethylene oxide or gas plasma sterilization (see Chapter 10) is recommended, as heat and chemicals will dull the blade. Disposable scalpels with nondetachable blades are occasionally used in the field for bandage removal. In a surgical procedure that requires no other instruments, such a scalpel may be used instead of opening an entire set of instruments.

**High-Energy Scalpels**

High-energy cutting instruments include the electrosurgical scalpel, the plasma scalpel, the water scalpel, and various forms of lasers. Although their energy sources differ, they share a common cutting mechanism. Energy is focally transmitted to tissue, and the effect depends on the water content of the tissue. The result is vaporization of cells along the line of energy application, a variable degree of thermal necrosis of the wound edges, and a relatively bloodless incision. Electrosurgical incisions are by far the most frequent applications of high-energy cutting.

Electrosurgery uses radiofrequency current to produce one or more of the following effects: incision, coagulation, desiccation, or fulguration of tissues. Most modern electrosurgery units use controlled high-frequency electrical currents ranging between 1.5 and 7.5 mHz. The predominant effect depends on the waveform of the current. Continuous undamped (fully rectified, fully filtered) sine waves provide...
maximal cutting and minimal coagulation, and they produce the least amount of lateral heat and tissue destruction. On the other hand, interrupted damped (partially rectified) sine waves maximize coagulation and minimize cutting capabilities. Modulated, pulsed (fully rectified, nonfiltered) sine waves allow simultaneous cutting and coagulation, or “blended” function. The magnitude of the selected effect is directly proportional to the duration and power (in watts) of the applied current.

Because most modern units can be used with unipolar and bipolar instruments, adequate electrical grounding of the patient is required for the unit to function properly in the monopolar mode (Fig. 12-4). The desired function (cutting or coagulation) can be selected by activating a button on the handle. Cutting and coagulation tips are available and can be exchanged as desired. Frequently, needles are used for cutting tissue because of their limited contact area with the tissue, which reduces the amount of tissue necrosis. Correct technique dictates that the tissue be placed under tension and that the contact area of the point be minimized to prevent adjacent tissue destruction. Skin and fascia incise easily, whereas muscle and fat are more easily incised using a cold scalpel. Units can also be used to coagulate vessels less than 1 mm in diameter (see Chapter 13). Coagulation time should be minimized to limit the amount of tissue destruction. The bipolar forceps for direct coagulation of smaller vessels speed up hemostasis, because the initial placement of a hemostatic forceps can be bypassed.

**Scissors**

Surgical scissors are available in various lengths, weights, blade types (curved or straight), cutting edge types (plain or serrated), and tip types (sharp-sharp, sharp-blunt, and blunt-blunt). The two most commonly used operating scissors for tissue dissection are the Mayo and the Metzenbaum scissors (Fig. 12-5). The sturdier Mayo scissors, available in 14- to 22.5-cm (5½- to 9-inch) lengths, should be used for cutting connective tissue. Metzenbaum scissors are reserved
for delicate soft tissue dissection and should not be used for dense tissue dissection. They are available in 12.5- to 34-cm (5- to 14\(\frac{1}{2}\)-inch) lengths.

Specially designated and marked suture scissors are used during surgery to cut the sutures. It is important to use only the suture scissors for cutting sutures, because this job rapidly dulls the blades, making them less effective for soft tissue dissection. The Olsen-Hegar needle holders are equipped with cutting edges (see later) to cut sutures, which obviates the need for a special set of suture scissors. Suture removal scissors (Fig. 12-6, A) are lighter in weight, and they have a sharp, thin point and a concave lower blade that facilitates blade placement underneath the suture, which reduces suture tension as it cuts. Wire-cutting scissors (see Fig. 12-6, B) have been designed specifically for wire suture removal and are typically short and heavy and have serrated blades.

Of the bandage scissors, the Lister and the all-purpose utility scissors are the best known (see Fig. 12-6, C). The lower blade of these scissors has a blunt tip that allows it to be inserted underneath the bandage without damaging the patient’s skin. The all-purpose scissor comes with a needle destroyer and a serrated blade (see Fig. 12-6, D). The serrated blade reduces bandage material slippage during cutting. Both scissors can be autoclaved.

As a general rule, scissors should be used only as intended by their design. Misuse dulls the edges and causes blades to

separate, rendering them ineffective. Properly functioning scissors should open and close with a smooth, gliding action, and their tips should meet when closed. Scissors should be sharpened only by a qualified person. Incorrect blade sharpening causes the metal to overheat and lose temper, and the cutting edges to become soft, resulting in loss of a sharp edge. Scissors with tungsten carbide inserts maintain sharpness longer. The insert can be replaced when dull.

**Needle Holders**

A needle holder is selected on the basis of the type of tissue to be sutured, the needle and suture material used, and personal preference. The grasping surfaces of the needle holders are crosshatched with a central longitudinal groove that facilitates the holding of curved suture needles. The two most commonly used needle holders are the Mayo-Hegar and the Olsen-Hegar (Fig. 12-7). The Olsen-Hegar is a combination of needle holder and scissors. It allows the surgeon working without an assistant to place, tie, and cut suture material swiftly. Its major disadvantage is the occasional inadvertent and premature cutting of suture material, which occurs usually from inexperience with the instrument. Both needle holders are available in various lengths and jaw widths. The choice of jaw width is based on the size of the needle. Narrow jaw widths are recommended for small needles to prevent needle flattening as the ratchet is tightened, whereas wider jaws prevent larger needles from rotating as they pass through dense tissue.

The Mathieu needle holder is also popular in equine surgery. It lacks finger holes and has an open box lock that is released by further closing of the handles. Unfortunately, this can occur when a firm grip is applied to the instrument while passing a needle through resistant tissue, making its use somewhat restricted. The efficient use of this needle holder requires practice.

The needle holder is the instrument that receives the most use, and through its constant metal-on-metal action, the most wear. It is advisable to purchase good-quality needle holders with tungsten carbide inserts that facilitate needle grip and instrument durability. The inserts lack a longitudinal groove and are designed with pyramidal teeth to provide a nonslip grip on needles. Instrument life can be prolonged by choosing the appropriate needle for the size of the needle holder. The lock box will be damaged if the instrument is used to grasp too large a needle. Repair is necessary if the needle can be rotated by hand when the instrument is locked at the second ratchet position. New needle holders will hold an appropriate-size needle securely when locked in the first ratchet tooth.

**Forceps**

Forceps are available in many designs, each intended to perform specific functions or tissue manipulations. They range from simple thumb forceps to instruments containing various hinge configurations and ratchet locks. Selection of appropriate forceps for inclusion in surgical packs can greatly facilitate some maneuvers. Improper use can compound tissue trauma during surgery, increasing inflammation and delaying healing. Also, improper use may alter the shape of the jaws, rendering them useless for the intended application.

**Thumb Forceps**

Thumb forceps (Fig. 12-8) are designed to grasp and hold tissues and small objects, such as suture needles, and thus...
they serve as an extension of the surgeon’s fingers. They consist of two blades attached at the proximal end, and the tips come together to hold tissue as finger pressure is applied on the blades. The outer surfaces of the blades are grooved to increase digital purchase. Thumb forceps are distinguished by the configuration of the tips. Forceps with smooth tips (without grooves or teeth) crush tissues because a considerable amount of force is necessary to gain purchase on the tissues. These smooth-tipped forceps are called traumatic (or anatomic) thumb forceps and should not be used for surgery.

A variety of serrated and toothed (or surgical) thumb forceps are available. The serrations and teeth allow a secure hold on tissues with minimal digital crushing pressure. The most aggressive of the thumb forceps is the rat tooth forceps (see Fig. 12-8, A), which is available with 1-to-2 to 4-to-5 interlocking tooth patterns. They are used primarily for manipulating skin and tough connective tissue. The Adson forceps has a 1-to-2 toothed tip but affords precise control of instrument pressure (see Fig. 12-8, B). The Adson forceps is used to grasp thin skin and light fascial planes. The Brown-Adson forceps has two longitudinal rows of small, fine, intermeshing teeth (see Fig. 12-8, C). The tooth configuration provides a broad but delicate tissue grip and facilitates grasping of the suture needle. The Russian forceps, which is not so frequently used, is very sturdy (see Fig. 12-8, D). It has a broad, round tip with a grooved perimeter and a concave center. This thumb forceps has a grip that is considered less traumatic than the Adson and Brown-Adson forceps, because pressure on the tissues is spread out over a larger area and it lacks teeth, making it less likely to tear or puncture tissue. The DeBakey and Cooley forceps lack teeth but are still considered atraumatic forceps because of the serrations in the tips (Fig. 12-9). These forceps are designed with longitudinal grooves and fine, horizontal striations that grip tissue without injury. They are considered ideal for vascular, thoracic, and intestinal surgeries. The DeBakey and Cooley serrated groove patterns are also available on hemostatic forceps.

**Hemostatic Forceps**

Hemostatic forceps are crushing instruments, designed to collapse vessels until hemostasis occurs or until electrocoagulation or ligation is accomplished (Fig. 12-10). Most of these forceps have transverse grooves on the inner jaw surface that increase tissue purchase. The Halstead mosquito forceps (see Fig. 12-10, A) are the smallest and most frequently used of these. They are available in 9- and 12.5-cm (3½- and 5-inch) lengths, with thin or standard-width, curved or straight jaws. They should be used only on small vessels. The Kelly and Crile forceps (see Fig. 12-10, B and C) are sturdier hemostatic forceps. These instruments are available in a standard 14-cm (5½-inch) length, with curved or straight jaws. The two differ in that the Kelly’s transverse grooves are restricted to the distal half of the jaw, whereas the Crile’s entire surface is grooved. Both are used for manipulating larger vessels.

To clamp large tissue bundles and vessels, Rochester-Pean forceps (see Fig. 12-10, D) are recommended. They have deep transverse grooves over the entire jaw surface, are available in 14- to 30-cm (5½- to 12-inch) lengths, and come with straight or curved jaws. Rochester-Carmalt forceps (see Fig. 12-10, E) are made to assist in pedicle ligation. Their jaw grooves run longitudinally with a few horizontal cross-striations at the tips. The groove design facilitates removal during ligation. Rochester-Ochsner forceps (see Fig. 12-10, F), available in 18.5- to 25-cm (6½- to 10-inch) lengths and with curved or straight jaws, are similar in design to the Rochester-Pean, but they differ by having 1-to-2 interdigitating teeth located at the jaw tip to help prevent tissue slippage. Ochsner forceps are considered traumatic.
and should be reserved for use on tissue that is to be removed.

**Tissue Forceps**

Tissue forceps (Fig. 12-11) are available in many shapes and sizes, and for a variety of uses. *Doyen* intestinal forceps, when properly used, are the least traumatic to tissue (see Fig. 12-11, A). They are manufactured with slightly bowed, flexible jaws with longitudinal serrations. The longitudinal serrations allow easy removal from the intestine. The instrument is available in 16.5- to 22.5-cm (6 1/2- and 9-inch) lengths with straight or curved jaws, and it can be obtained with a wing nut to secure the tips in a clamping position, which is especially useful for longer forceps. The tips of the jaws should just meet when the ratchet’s first tooth is engaged. The instrument will traumatize tissue if the ratchet is closed too tightly.

*Allis* tissue forceps vary in length between 12.5 and 19 cm (5 and 7 3/4 inches) and in the number of teeth (4-to-5 and 5-to-6) (see Fig. 12-11, B). Designed to grip tissue, the teeth are oriented perpendicular to the direction of pull. The teeth can be traumatic, especially when excessive compression is applied to the handles, and his forceps should be used only on heavy tissue planes or on tissue that is to be excised.

*Babcock* intestinal forceps, like the *Allis* tissue forceps, pull in a direction that is perpendicular to the tissue, but the *Babcock* forceps are considered less traumatic (see Fig. 12-11, C). The instrument is available in lengths from 13 to 24 cm (5 3/4 to 9 1/2 inches) and jaw widths of 6 to 10 mm. *Lahey* right-angled forceps (see Fig. 12-11, D), *Vulsellum* uterine forceps (see Fig. 12-11, E), and *Noyes alligator* forceps (see Fig. 12-11, F) are infrequently used, but their unique designs make them useful in a variety of surgical applications.

Hemostatic and tissue forceps should regularly be inspected for instrument wear and damage. When the instrument is closed, the jaws should align perfectly and the teeth, if present, should interdigitate. When clamped on tissue, the instrument should not spring open.

**Retractors**

Soft tissue retractors are designed to spread the wound edges to facilitate exposure of the surgical field. A classification used by many manufacturers includes the finger-held, the hand-held, and the self-retaining retractors. All three types require an adequate length of incision to prevent tissue tearing when retraction is used. The finger-held and hand-held retractors require a surgical assistant.

**Finger-Held Retractors**

*Senn, Mathieu, Meyerding, Farabeuf,* and *Parker* retractors are typical representatives of this group (Fig. 12-12). *Senn* and *Mathieu* retractors are similar (see Fig. 12-12, A and B). Both are available with either blunt or sharp retractor prongs at one end and a right-angled fingerplate on the other. These retract skin and superficial muscle layers but are less useful for retracting a large muscle mass. *Meyerding* finger retractors (see Fig. 12-12, C) have an assortment of gripping blades available and a single-ring handle. *Farabeuf* and *Parker* retractors (see Fig. 12-12, D and E) are larger, with deeper, flat blades on both ends that allow the retraction of more tissue.
Hand-Held Retractors

Common hand-held retractors are the Army-Navy, Hohmann, Meyerding, and Ribbon retractors (Fig. 12-13). Army-Navy retractors are available in a standard 21.5-cm (8 1/2-inch) length (see Fig. 12-13, A). They have double-ended retracting blades of two different lengths, which allow the surgeon to select a blade according to tissue depth. Hohmann retractors are available in 16.5- to 24.5-cm (6 1/4- to 9 3/4-inch) lengths, and with blade widths from 6 to 70 mm (see Fig. 12-13, B). The blade has a blunt projection that is useful in exposing bone while retracting the muscle in orthopedic and reconstructive procedures. Meyerding retractors are available with three different blade widths and depths (see Fig. 12-13, C). The largest blade is 9 cm (3 1/2 inches) wide and 5 cm (2 inches) in depth. Ribbon malleable retractors are 32.5 cm (13 inches) in length and available in 2- to 5-cm (1/4- to 2-inch) widths (see Fig. 12-13, D). The malleable blade can be bent repeatedly, making it a favorite of some surgeons. After prolonged use, it becomes an unaesthetic surgical instrument, although its effectiveness is not altered.

Self-Retaining Retractors

The Gelpi, Weitlaner, Balfour, and Finochietto retractors (Fig. 12-14) are representatives of the available self-retaining retractors. The Gelpi retractor has a grip-lock mechanism...
that maintains tension on its two outwardly pointed tips (see Fig. 12-14, A). The instrument is available in a 14-cm (5 1/2-inch) pediatric size and a 17-cm (6 3/4-inch) standard size. The larger version is available with ball stops to prevent excess tissue penetration. Weitlaner retractors range in size from 10 to 23.5 cm (4 to 9 1/2 inches) and are available with 2-to-3 or 3-to-4 outwardly pointed blunt or sharp teeth (see Fig. 12-14, B). A 14-cm (5 1/2-inch) Weitlaner is also available with solid blades (see Fig. 12-14, C). The Beckman-Weitlaner hybrid has blunt or sharp 3-to-4 teeth and hinged jaws (see Fig. 12-14, D). The hinge facilitates seating the instrument deep in the incision. The Balfour self-retaining abdominal retractor is available in 17.5- to 25-cm (7- to 10-inch) spreads and with 6.5- to 10-cm (2 1/2- to 4-inch) deep, solid or fenestrated side blades (see Fig. 12-14, E). Finochietto rib spreaders have two bladed arms that are spread apart by a strong ratchet system (see Fig. 12-14, F). The blunt-ended blades are a standard 48 mm deep by 65 mm wide. The
instrument is available with maximum spreads of 20, 25, or 30 cm (8, 10, or 12 inches).

**Towel Clamps**
Several types of towel clamps are available (Fig. 12-15). Backhaus and Roeder towel clamps are the most commonly used (see Fig. 12-15, A and B). The Roeder clamps have ball stops to prevent deep tissue penetration and minimize towel slippage. The Backhaus clamp is available in 9- and 13-cm (3½- and 5½-inch) sizes, whereas the Roeder is available only in the larger size. The Lorna towel clamps are non-penetrating and therefore ideal for securing suction lines and cables to drapes (see Fig. 12-15, C). Penetrating towel clamp tips should meet when closed, and they should be sharp and free of burrs.

**Suction Tips**
There are three basic types of suction tips available (Fig. 12-16). The Yankauer tip is relatively large, allowing the removal of large volumes of blood or fluid from the surgical site (see Fig. 12-16, A). The Frazier-Ferguson tip has the smallest diameter and is useful when working in confined areas (see Fig. 12-16, B). The suction intensity of these tips can be varied by placing the index finger over the hole located on the handle. Both models are available in stainless steel and in disposable plastic. The Poole suction tip has multiple ports along the tube, making it ideal for use within the abdomen, where single-orifice tubes are easily plugged by omentum (see Fig. 12-16, C).

**ORTHOPEDIC INSTRUMENTS**
A wide variety of instruments are associated with orthopedic surgery. Those presented here are used outside the realm of fracture repair. For information regarding instruments used for reconstruction and fracture treatment, the reader is referred to Chapter 81.
Curets

Curets are easily recognized by their cuplike structure (Fig. 12-18). The sharp, oval or round edges are useful for removing diseased bone, debris, and damaged tissue from dense tissue surfaces. Their shape also makes them ideal for harvesting cancellous bone grafts. Several sizes of curets are available. The Spratt curets have a single oval cup at the end of a grooved handle, whereas the Volkman curets are double ended, having an oval cup on one end and a round cup on the other.

Periosteal Elevators

As their name suggests, periosteal elevators are designed to elevate periosteum and muscle attachments away from bone. Common elevators include the single-ended Langenbeck and Key elevators and the double-ended Sayre and Freer elevators (Fig. 12-19). The Langenbeck elevator is available with either a blunt or a sharp tip, whereas the Key elevator has only a blunt tip, but it comes in widths of up to 2.5 cm (1 inch). The double-ended elevators are narrow and have one end that is blunt and one that is sharp.

Bone-Cutting Instruments

Osteotomes, chisels, and gouges are all hand-held instruments that are used in combination with a mallet (Fig. 12-20). Gouges are easily distinguished by their concave shape. They are available in 4- to 38-mm widths. Osteotomes

Figure 12-18. Curets. A, Spratt curet, with available cup sizes. B, Volkman curet, with available cup sizes. (Reprinted with permission from Miltex Instrument Company, Bethpage, NY, 2004.)
are double-beveled at their cutting tip, and chisels are single beveled. The cutting widths vary from 4 to 38 mm. The chisel tends to move in a direction away from the beveled edge. Therefore, it needs to be applied at a somewhat steeper angle relative to its axis. This allows the chisel to move along the bone surface on its beveled edge. If the chisel is reversed, it tends to dive into the bone, leaving sharp edges on the surface. The chisel is the preferred instrument to remove exostoses, but when the direction of bone cutting needs to be more precise, it is better controlled with an osteotome. Common types for these three cutting instruments are Army-Navy, Hibbs, and Smith-Petersen.

The mallet can be solid stainless steel or have an aluminum handle and a stainless steel head. Polyethylene-capped stainless steel heads are quieter and prevent the production of metal particle flake.

Bone-cutting forceps can be of the single- or double-action type, straight or angled. The Liston forceps are representatives of the single-action type, and Ruskin and Stille-Liston are double-action bone-cutting forceps (Fig. 12-21).

Trephines

Two types of trephines are available, Michele and Galt (Fig. 12-22). Both are T-shaped and capable of drilling a cylinder of bone. The Michele trephine is available in graduated inner diameters of 0.6 to 3.1 cm (1/4 to 1 1/4 inch). It contains a graduated scale along its shaft, allowing the penetration depth to be measured. It cuts through bone on the end of the shaft only. The Galt trephine can cut bone at the end of the shaft and along the outside perimeter of the shaft. It is available in graduated sizes from 1.25 to 2.5 cm (1/2 to 1 inch) in diameter and has an adjustable central trocar. The trocar centers the trephine and stabilizes it until a circular trough is cut in the bone.

MICROSURGICAL INSTRUMENTS

Presently, reconstructive vascular and neural surgery is rarely performed in equine patients. The exceptions are thrombectomies, which may be performed with the help of catheters (see Chapter 14). Because horses are rarely used as research animals, microsurgical techniques play a minor role in these aspects. The microsurgical instruments used for ocular surgery can be found in Chapter 55.
INSTRUMENT MAINTENANCE

Proper care maintains long-term instrument serviceability. Instruments should be cleaned immediately after use. Care should be taken to separate sharp and delicate instruments from other instruments that may damage them. When washing them by hand, it is best to use warm water, a neutral-pH detergent, and a soft bristle brush. Ultrasonic cleaners are more effective than hand washing; however, the manufacturer’s recommendations for type of water, such as deionized or distilled, and detergent used should be followed (see “Cleaning” in Chapter 10). If cleaning cannot be done immediately, instruments should be submerged, in the open...
position, in a solution of water and neutral-pH detergent. Hard water, saline solution, and non-neutral-pH detergents (dish washing liquids) should be avoided, because surface discoloration, corrosion, and poor mechanics of the joints may result. Once cleaned, instruments should be rinsed with de-ionized or distilled water. Instruments with a working action should then be treated with an instrument lubricant (instrument milk). The lubricant, which often includes a rust inhibitor, should not be rinsed off. Instruments are then dried and stored or resterilized.

Instrument refurbishing programs are available through most instrument manufacturers. In addition to resharpening cutting edges and replacing tungsten carbide inserts, instruments are cleaned, polished, and refinished to retard corrosion. Refurbishing generally costs less than replacement.

IDENTIFICATION
Instruments are frequently marked to identify their owner or their belonging to an instrument set. Various identification methods are available. Commercially available engravers should be avoided, as should any other method that damages the surface of the instrument. Surface damage, with removal of the corrosion-resistant coating, will shorten instrument life. Electrochemical etching units are acceptable as long as they are properly used. After etching, the instrument must be thoroughly rinsed to neutralize the acid etching fluid.

Autoclavable plastic tapes for instrument identification are available in different colors and are easy to apply. Color coding with tape does not harm the instrument surface. All instruments belonging to a specific set can be marked with the same color. This is helpful in large clinics, where different surgical teams work parallel to each other with different instrument sets. During cleaning and resterilization, instruments belonging to different sets may be mingled. The color coding allows easy and efficient separation. Poorly applied tape, however, may begin to peel off, creating crevices that could harbor debris and microorganisms. Proper selection of a tape marking system should include considerations of color, durability, and adhesive properties to ensure a long life once applied to the instrument. Higher-quality marking systems are frequently marketed through instrument manufacturing companies.

PACK PREPARATION AND STORAGE
Tightly woven linen drapes have long been used to package instrument sets. Their disadvantages include short shelf-life and the cost of laundering for reuse. Because microorganisms can fairly rapidly penetrate linen wrappers, it is prudent to double-wrap the sets with linens. Safe storage times have been established (see Table 10-1).

A variety of paper-type products have been developed to replace linen wrappers. Although these products share some of the disadvantages of linen, they offer longer safe storage times, because the sterilization process closes the pores within the sheet. As a result, these paper-type products cannot be reused and are therefore disposable, so laundry expenses are avoided. On the other hand, disposal costs and the burden on the environment through exhaust gases (e.g., CO₂) from incinerators rise. Many of the newer paper-type wrappers handle like linen.

Both paper and linen prevent visualization of the instruments within the pack. In the case of sets, this is not a problem because the contents are known. However, if instruments are separately wrapped, visualization is important. Therefore, special wraps that consist of a sheet of paper on one side and a clear plastic sheet on the other have become popular. The plastic side allows the instrument to be seen inside, and the paper side allows steam or ethylene oxide to penetrate the package. Sharp points of instruments have to be covered by plastic caps to prevent inadvertent damage to the paper layer. These wrappers are available in tube rolls in several sizes, and most of them contain sterilization indicators (see Chapter 10). The ends are heat sealed. Safe storage time is extended with this type of wrapping, but the paper side is still susceptible to microorganism penetration when wet.

Regardless of the type of wrapping chosen, the instruments should be loosely packed with the jaws slightly opened to allow circulation of steam, ethylene oxide, or gas.
plasma\(^2\) (Fig. 12-23). All instrument packs should be dated and labeled for easy identification, and for resterilization if they are not used within the safe storage timeframe. For prolonged storage life, the packs may be placed within a plastic envelope or into a glass closet.

Lately, reusable metal sterilization containers enjoy renewed popularity, after having almost disappeared in the late 1980s (SterisSet Containers, Wagner GmbH, Munich, Germany) (see Fig. 10-1). These containers are used for holding surgical instrument sets or textiles during vacuum-steam sterilization procedures, and for maintaining sterility of the contents during storage and transport under hospital conditions. They operate with either filters or valves. The filter units are single-use filters, or reusable textile filters with known service life spans. SteriSet valve containers have a closed base and permanent stainless steel pressure-sensitive valves in the inner lid. The sterilization valves react to the change in pressure during the sterilization process. During the vacuum phase, the valves open upward, and the air/steam mixture can escape from the container. During the pressurization phase, the valves open inwardly and allow steam to enter the container. The system is automatically flushed and sterilized by the hot steam rushing through the valve with every sterilization cycle. Outside the sterilizer (i.e., during storage or transport), the valve is closed and serves as a barrier to microorganisms.

**Surgical Techniques**

Jörg A. Auer

Surgery can be defined as goal-oriented violence to tissue and, therefore, considerations related to minimizing tissue damage are an important part of adequate preoperative planning and proper surgical technique.\(^1\) Adequate preparation for each surgery is the best prevention of unnecessary delays that prolong surgery. Before embarking on an unfamiliar or complicated surgical task, the operator should plan the procedure in a step-by-step manner from skin incision to closure. This chapter describes those aspects of surgical manipulations that are basic to the performance of any procedure—namely, the different techniques of incision, excision, and dissection of tissue, in addition to the methods of surgical hemostasis, tissue retraction and handling, and surgical irrigation and suction. Adherence to the basic principles of state-of-the-art surgical technique, described by Halsted, minimizes tissue trauma, blood loss, and wound dehiscence, resulting in a better surgical result.\(^2\)

**BASIC MANIPULATIONS OF SURGICAL INSTRUMENTS**

Incising or cutting into tissue represents the initial step of every surgical intervention. The instruments used for this procedure and the manner in which they are applied provide the surgeon with the means to vary the type of incision and its effects on the surrounding tissue. The scalpel and scissors are the basic instruments for incising or excising tissues. Separation along tissue planes is usually accomplished through blunt dissection. Electrosurgery and laser surgery complement the instruments used for incisions and excisions.

**Scalpels**

**Steel Scalpel**

The steel scalpel with disposable blades is the instrument most frequently used to incise skin and other soft tissues. It is prudent to apply the blade to the scalpel handle with the help of a needle holder or similar instrument to prevent inadvertent puncture of the surgery gloves, or even worse, cutting of the surgeon’s fingers.

There are three ways to hold the blade handle: the pencil grip, the fingertip grip, and the palm grip.\(^3\) With the pencil grip, very precise cuts can be performed. The distal end of the scalpel handle is grasped between the thumb and index finger and rests on the middle finger, while the tip of the middle finger contacts the patient (Fig. 13-1). The surgeon’s hand also rests lightly on the patient and the fingers are moved rather than the entire arm, which allows better control of the blade. This grip works best for short incisions where precision is important.\(^4\) Contact with the patient controls precisely the depth of penetration. The disadvantage of this grip compared with the others is the relatively steep angle with which the scalpel is held, thereby decreasing cutting edge contact with the skin.

For the fingertip grip, the tips of the third, fourth, and fifth fingers are placed underneath the handle, while the tip of the thumb is placed on the other side. The index finger...

CHAPTER 13
Surgical Techniques
Jörg A. Auer

Surgery can be defined as goal-oriented violence to tissue and, therefore, considerations related to minimizing tissue damage are an important part of adequate preoperative planning and proper surgical technique. Adequate preparation for each surgery is the best prevention of unnecessary delays that prolong surgery. Before embarking on an unfamiliar or complicated surgical task, the operator should plan the procedure in a step-by-step manner from skin incision to closure. This chapter describes those aspects of surgical manipulations that are basic to the performance of any procedure—that is, the different techniques of incision, excision, and dissection of tissue, in addition to the methods of surgical hemostasis, tissue retraction and handling, and surgical irrigation and suction. Adherence to the basic principles of state-of-the-art surgical technique, described by Halsted, minimizes tissue trauma, blood loss, and wound dehiscence, resulting in a better surgical result.

BASIC MANIPULATIONS OF SURGICAL INSTRUMENTS
Incising or cutting into tissue represents the initial step of every surgical intervention. The instruments used for this procedure and the manner in which they are applied provide the surgeon with the means to vary the type of incision and its effects on the surrounding tissue. The scalpel and scissors are the basic instruments for incising or excising tissues. Separation along tissue planes is usually accomplished through blunt dissection. Electrosurgery and laser surgery complement the instruments used for incisions and excisions.

Scalpels
Steel Scalpel
The steel scalpel with disposable blades is the instrument most frequently used to incise skin and other soft tissues. It is prudent to apply the blade to the scalpel handle with the help of a needle holder or similar instrument to prevent inadvertent puncture of the surgery gloves, or even worse, cutting of the surgeon’s fingers.

There are three ways to hold the blade handle: the pencil grip, the fingertip grip, and the palm grip. With the pencil grip, very precise cuts can be performed. The distal end of the scalpel handle is grasped between the thumb and index finger and rests on the middle finger, while the tip of the middle finger contacts the patient (Fig. 13-1). The surgeon’s hand also rests lightly on the patient and the fingers are moved rather than the entire arm, which allows better control of the blade. This grip works best for short incisions where precision is important. Contact with the patient controls precisely the depth of penetration. The disadvantage of this grip compared with the others is the relatively steep angle from which the scalpel is held, thereby decreasing cutting edge contact with the skin.

For the fingertip grip, the tips of the third, fourth, and fifth fingers are placed underneath the handle, while the tip of the thumb is placed on the other side. The index finger...
rests on the top surface of the blade to create controlled, downward pressure (Fig. 13-2). This grip is useful for long straight, curved, or sigmoidal incisions, because it places the long surface of the blade against the tissue, providing greater cutting surface, better control of the blade angle, and optimal control of incision depth. The blade movement originates in the shoulder, with the entire arm participating in directing the incision.5

The palm grip is not commonly used. Some surgeons prefer it for standing flank incisions. It provides the strongest grasp of the scalpel. The scalpel is grasped with the fingers and palm wrapped around the handle, while the thumb is placed on the top edge of the blade to create downward pressure (Fig. 13-3). The small finger is resting on the patient to steady the hand.

Electro Scalpel
Proper cutting technique with the electro scalpel (see Fig. 12-4) differs markedly from that with the steel scalpel. A modified pencil grip is used to hold the instrument almost perpendicular to the tissue surface to be cut, to minimize the area of energy contact at the point of incision. The use of a needle scalpel further minimizes the contact area. The hand piece is held between the thumb and the middle finger tips, leaving the index finger free to activate the trigger button of the hand piece.

Scissors
Operating scissors cut tissues by moving edge contact between two blades that are set slightly toward one another.6 This action is most effective near the tips of the instrument, dictating their use for precise tissue cutting. Tissues that are too thick or too dense to be cut with the tips of the scissors should be separated with either a larger pair of scissors or a scalpel blade. The blade near the hinge should not be used for cutting, because the tissues are crushed more than cut, resulting in devitalization.

As shown in Chapter 12, many scissors are available with straight and slightly curved blades. The mechanical aspect of scissors is best achieved with straight blades, so straight-bladed scissors should be used in dense tissues. Curved scissors provide a more comfortable positioning of the surgeon’s hand and better visualization of the tips in deeper planes, but these instruments are less efficient in cutting tissues.

The classic tripod grip provides the best functional result. The tip of the thumb and last digit of the third finger are placed in the rings of the scissors, while the index finger stabilizes the instrument along the shaft toward the tip of the blades (Fig. 13-4). The tripod formed by the thumb, third finger, and index finger creates a stable and powerful base for cutting.

Suture scissors are usually held in the classic tripod grip to cut the sutures at the designated spot. Because it is the surgeon who is responsible for the lengths of the suture ends, an adequate length must be presented to the assistant so that the scissors can be applied at the desired spot.

A surgeon working without an assistant may use a pair of Olsen-Hegar needle holders with the built-in suture scissors, or the suture scissors can be held in the same hand as the needle holders in the manner described for handling multiple hemostats (see later).
Needle Holders

There are two methods for holding needle holders. One is the classic tripod grip just described for scissors. This method works best when precise suture placement is indicated. The other is the palm grip, which is useful for rapid instrument manipulation in closure of tissue when precision is not essential; however, the palm grip is not universally accepted as proper technique.3 With the palm grip, also referred to as the modified thenar eminence grip, the surgeon places the instrument in the palm of the hand with the one ring resting against the thenar eminence of the thumb. The index finger stabilizes the instrument along the shaft. The lock mechanism is disengaged by lateral pressure applied to the instrument using the thenar eminence. The tips of the instrument may be opened and closed by adduction and abduction movements of the thumb. This method of manipulation is useful for rapid closure, because it allows the needle to be more easily grasped, extracted, and readied for the next pass.7

A needle holder grips the suture needle along its shaft so that the needle is perpendicular to and near the tip of the instrument. The needle is usually grasped mid-shaft, but it can be grasped closer to the needle tip for greater precision.7 The needle is passed through tissue by rotation of the surgeon’s hand, always following the curve of the needle. Care should be taken to advance the needle so that it protrudes out of the tissue enough to allow the needle holder or tissue forceps to grasp it far enough behind the tip to prevent dulling or bending of the needle. When using the needle holder, the surgeon may pronate the hand for greater precision or supinate the hand for greater speed.7

Forceps

Thumb Forceps

Thumb tissue forceps are used to manipulate and stabilize tissue during incising and closing. Thumb forceps are usually held in the nondominant hand using a pencil grip. When not in use, they may rest in the palm.7 If the surgeon’s hand becomes fatigued, the natural tendency is to switch to a palm grip. This grip is less precise and more likely to incite unnecessary tissue trauma.

When closing deep tissue layers, thumb forceps are useful for retracting superficial layers during needle placement, starting on the far side of the incision (Fig. 13-5). As the needle is passed, the forceps moves to the layer being closed, exposing the exit point. The process continues with the tissue forceps being used to grasp tissue layers in opposite order on the near and far side of the incision.7

Hemostat Forceps

Mosquito and other tissue forceps used for hemostasis are held in the classic tripod grip to grasp the vessel to be ligated. When a surgical assistant is not available and several hemostats have to be applied, time can be saved by introducing the ring finger through the left ring of several such instruments and holding them in the palm of the right hand, while applying a hemostat to a vessel in the tripod grip with the same hand (Fig. 13-6). By arranging the hemostats so that the tips point toward the thumb, the instru-

Figure 13-5. Proper technique for holding and using thumb forceps.

ments can one by one be rotated into the tripod grip and applied to a bleeding vessel.

Tissue Forceps

The most commonly used tissue forceps in equine surgery are towel clamps, mosquito forceps, Allis tissue forceps, Ochsner forceps, and Carmalt forceps. All these forceps are applied to tissues with the tripod grip. Towel clamps are useful during some procedures for tissue manipulation even though their primary purpose is to secure drapes on the patient. Towel clamps attached to skin edges provide an atraumatic method of retraction for exposing deeper tissues. Because Allis tissue forceps and Ochsner forceps are traumatic and crush the tissue, they are best reserved for securing tissue that can be excised.

TISSUE INCISION AND EXCISION

Slide Cutting

The skin is usually incised with a scalpel because this is the method that is least traumatic and most conducive to primary healing. The incision should be made in one smooth pass of the scalpel through the skin, using the slide-cutting technique, transecting the dermis without cutting deep
fascial tissue. The surgeon’s free hand should stabilize and stretch the skin being incised (Fig. 13-7). When properly transected, skin edges will retract. In a longer incision, it may be necessary to reposition the free hand to put tension on the skin along the entire incision. During this repositioning, the scalpel should not be lifted from the tissues. Each time the scalpel leaves and returns to the tissue, a jagged edge is created that will adversely affect healing (Fig. 13-8).

Stab or Press-Cutting Incision

Stab or press-cutting incisions are generally performed with the scalpel held in the pencil grip in a vertical position (Fig. 13-9). A stab incision results when the bursting threshold of the tissue being incised is exceeded. Press cutting is applied to initiate incisions into hollow, fluid-filled structures, such as the bladder. For this technique to be effective, the tissue to be entered should be under tension. Press-cutting incisions are also used frequently during screw fixation of an anatomically reduced condylar fracture of MCII/MTCII or of the proximal phalanx. The scalpel is held in a pencil or palm grip, perpendicular to the surface of the tissue. The tissue is entered with a slight thrust, and the incision is extended carefully by pushing the cutting edge of the scalpel through the tissue. With this technique, depth control is poor, but it can be improved by using the index finger as a bumper (Fig. 13-10), effectively limiting penetration of the blade to a predetermined depth.7 Press cutting with an inverted blade (Fig. 13-11) elevates the tissues to be transected and provides more safety for the deeper-laying structures, while preventing fluid from exiting a fluid-filled structure or organ.

Two rarely applied techniques are the sawing (or push-pull slide cutting) and the scalpel scraping technique, the latter of which is used to separate fascial planes or for subperiosteal dissection and elevation of muscles.7
Scissor Incisions

The scissor tips are often used to transect tissues. Before this technique is used, the tissue to be incised must be isolated from underlying tissues using blunt scissor dissection (see later). This isolates the tissue structures to be cut. Some tissues can be effectively transected by partially opening the scissors, holding the blades motionless relative to each other, and pushing them through the tissue. Allowing the scissors to slide through the tissue creates a clean, atraumatic incision. This method is appropriate for opening fascial planes over muscles or subcutis, or for opening tissue planes in which the start and finish points of the incision are well defined.

Electroincision

Because lateral heat production during electroincision increases with the duration of trigger activation and tissue contact time, the blade is moved at a speed of about 7 mm/s. Only one tissue plane is cut at a time, using only the tip of the blade. Depth control with the electro scalpel is less precise than with the cold scalpel. Because the electrode cuts all tissue it contacts, visual control is of paramount importance. Electrosurgical incision should not be used in areas with ill-defined anatomic planes. Thermal necrosis at the wound edges can be reduced and depth control can be improved by using the lowest setting on the controls that allows clean cutting.

The electrode should be cleaned frequently to ensure proper function. Charred tissue that accumulates at the tip of the electrode acts as an insulator and decreases effective cutting. Three undesirable effects are associated with a charred electrode: (1) higher power is required to incise tissues, (2) current is dispersed to a larger area of tissue, diminishing control, and (3) thermal necrosis of the wound edges is increased. If the buildup of charred material at the tip is rapid or excessive, the power setting may be too high or the cutting speed may be too slow.

Advantages reported for electrosurgical incisions over those made with a steel scalpel are (1) reduction in total blood loss, (2) decreased need for ligatures, and thus reduction in the amount of foreign material left in the wound, and (3) reduced operating time. These advantages come at the expense of delayed wound healing and decreased resistance of wounds to infection. Controlled experiments revealed that there is no overall difference in epithelial healing between incisions made with the electro scalpel and those made with the steel scalpel. However, a difference in the initial response of the connective tissue was recorded. Electro incisions of the skin heal primarily, but there is a definite lag time in reaching maximal strength. Because of this delay, skin sutures or staples should remain in place an additional 2 to 3 days if the incision was made with an electro scalpel. Electrosurgical incisions should be avoided in the presence of cyclopropane, ether, alcohol, and certain bowel gases because of the risks of ignition and explosion.

Tissue Excision

Most tissues are excised primarily by scalpels or scissors. Skin, hollow organs, contaminated subcutaneous tissues, and neoplastic tissues are best excised with a scalpel. This is performed by a single passage of the scalpel along or around the periphery of the tissue to be removed. However, repeated passes or a sawing action with the scalpel may be necessary to complete excision of the tissue. This is especially true for thick, dense tissue or en bloc excision. Precise excision of
BLUNT DISSECTION
Blunt dissection is used to reduce or prevent the risk of damaging deeper vital structures during a surgical approach. The technique is performed digitally or with surgical scissors. Blunt dissection is generally carried out along natural tissue planes or parallel to tissue fibers. Excessive dissection and undermining should be avoided, because creation of dead space impedes wound healing and potentiates infection. If scissors are used, the tips are placed in a closed position into the tissue, and the jaws are opened parallel to the tissue fibers or along natural tissue planes (Fig. 13-12). Forceps can be used to stabilize the tissue during dissection. When digital dissection is applied, the gloved index finger of each hand is placed side by side in the same tissue plane and pulled in opposite directions to stretch and separate the tissue, thus increasing surgical wound exposure.

Scissors are useful for dissecting tissues, especially the subcutaneous tissue. The plane of dissection is parallel with the skin, along the incision edges. Limited dissection underneath the skin allows further retraction of the skin away from the center of the incision and facilitates visualization of deeper tissues. Scissor dissection is less useful, and potentially dangerous, in deeper dissections, where vessels or nerves could be severed before they are seen.

SURGICAL HEMOSTASIS
Proper hemostasis prevents the surgical field from being obscured by blood, and it decreases the potential for infection. Hemostasis minimizes blood loss and postoperative hematoma or seroma formation, which may delay healing or potentiate wound dehiscence. Additionally, excessive or uncontrolled hemorrhage can lead to anemia or hypovolemic shock. Therefore, the goal of hemostasis is to prevent blood flow from incised or transected vessels. This is accomplished primarily by interruption of blood flow to the involved area or by direct closure of the vessel walls. There are mechanical, thermal, and chemical techniques to achieve hemostasis.

Mechanical Hemostasis
Pressure
Pressure can be applied directly over the site of a major vessel, or over a major vessel at a site remote from the wound, using the fingers or the hand. Oozing from small vessels is best controlled by direct pressure using sterile gauze. Although this is the least traumatic means of vascular hemostasis, it is not adequate for medium-size and larger vessels, which require some other means of hemostasis.

Gauze packing is used to control hemorrhage from open body cavities (such as the nasal cavity, paranasal sinuses, urogenital tract, and defects created in the hoof wall or sole) and from large body wounds. Hemorrhage is controlled through pressure, allowing time for clot formation. The gauze can be soaked in iced or chilled saline solution, or diluted epinephrine can be added to the saline solution to help control the bleeding. Several gauze rolls tied together may need to be used to effectively pack large defects. The end of the packing is best secured to the body to ensure its presence at the time of removal.

Ligatures
Hemostats can be applied to small, noncritical vessels and held there for a few minutes. The vessel tissue trapped in the jaws is crushed, effectively occluding the vessel. A combination of vasospasms and intravascular coagulation maintains hemostasis when the clamp is released. To facilitate these events, the vessel can be stretched or twisted before the instrument is released. If bleeding control from a critical vessel is necessary, atraumatic hemostatic clamps can be used to limit damage and allow repair.

Suture ligation is commonly used to control bleeding from larger vessels. Absorbable suture material is preferred over nonabsorbable material, as the latter can result in extrusion or sinus tract formation. The number of ligatures required to maintain occlusion depends on vessel size and the material used. A simple circumferential ligature is generally used for small vessels (Fig. 13-13, A), whereas pulsating or large vessels, such as arteries, should be ligated with two ligatures, a circumferential followed by a transfixation ligature placed more distally (Fig. 13-13, B). This will prevent the circumferential ligature from slipping.

In most situations, a hemostatic clamp is applied to the vessel prior to ligation. The clamp’s crushing effect facilitates ligature placement and vessel occlusion. The following steps for proper use of hemostatic forceps should be kept in mind:

1. The smallest forceps that will accomplish the needed hemostasis should be used.
2. Only as much tissue is clamped as is necessary.
3. The tip of the instrument should be used rather than the middle or the base.
4. The mosquito forceps should be applied to small bleeding vessels perpendicular to the cut surface.
5. Other forceps should be applied perpendicular to the long axis of the vessel to be ligated.

6. The mosquito forceps should be applied to surface bleeders so that they come to rest lateral to the incision, with the concave part of the curved blades pointing down. In deeper locations, such as in the abdominal cavity, the forceps should be placed such that the tips point upward.

7. The assistant should pick up the hemostat and direct it with the tip pointing toward the surgeon.

8. The hemostat should be held in the nondominant hand. One ring is held between the index finger and the thumb, and the other ring rests on the middle and ring fingers (Fig. 13-14).

9. At the time of the final tightening of the first half hitch around the vessel, the surgeon should give the assistant the sign to release the hemostat.

10. The assistant releases the hemostat by pushing up with the middle and ring fingers while pressing down with the thumb, carefully releasing the ratchet mechanism of the hemostat.

11. Before releasing the hemostat, the instrument should be directed into the incision to release tension on the vessel and prevent it from slipping out of the ligature before the ligature is completely tightened.

12. The surgeon should apply a second half-hitch over the first one, forming a square knot.

13. Then, the assistant should cut the suture ends at the level indicated by the surgeon, with the suture scissors held in the dominant hand. If double ligation is indicated, clamps are placed at each ligature site, approximately 2 to 3 mm apart. Once the vessel is clamped, a circumferential ligature is placed around the vessel adjacent to the proximal hemostat. As the ligature is tightened, the clamp is released. The ligature should fall into the area of the vessel crushed by the clamp. The distal clamp is released and replaced with a transfixation ligature.

Large pedicles are preferably divided into smaller units, and each is separately ligated. After ligating the last unit, a suture is placed around the combined units and tied as one pedicle ligation. This is called the “divide and conquer” method. The three-forceps method involves initial clamping of the pedicle with three parallel forceps 1 to 1.5 cm apart, incorporating the entire pedicle. The pedicle is transected between two such forceps, leaving one side with one forceps and the other with two forceps. A loose ligature is applied around the entire pedicle with the two forceps between the base of the pedicle and the first forceps. This forceps is then partially taken off, leaving a strand of crushed tissue behind. The ligature is now solidly tightened, making sure that it comes to lie over the crushed line of tissue. While the surgeon tightens the ligature, the assistant carefully removes the forceps completely. If the pedicle is too large, insufficient hemostasis is often achieved with this technique. In such cases, the “divide and conquer” technique should be used.

Ligation of vessels obscured by perivascular fat accumulation, such as occurs in the omentum, may be a challenge because occasionally the vessel is traumatized by trying to blindly pass a needle around the vessel. In these cases, the blunt end of the needle can be used to place the suture around the vessel. This part of the needle pushes the vessel aside if it is in its path rather than penetrating it. Subsequent ligation of the vessel is routine.

**Staples**

Vascular staples, which can be used to occlude vessels up to 7 mm in diameter, are an alternative to suture ligation. They offer the advantage of speed and precision in placement. A specially designed instrument (1) applies two vascular staples that are crimped around the vessel simultaneously and (2) divides the vessel between the staples (the ligate-and-divide stapler [LDS] is described in Chapter 17). In cases of extensive intestinal resection with multiple mesenteric arcades, time is saved using this instrument. Disadvantages of staples are potential failure when used on large vessels, and expense.
Surgical Repair

Management of lateral wall defects in vital vessels can be very difficult. Suturing the defect is recommended, incorporating the tunica, adventitia, and media—the major holding layers within the walls of large vessels. Fine suture material (4-0 to 6-0) is recommended, using a continuous pattern with bites placed close together.

Esmarch System

The Esmarch and pneumatic tourniquet systems are excellent methods of temporarily occluding blood flow to a distal extremity (Fig. 13-15). They are used to maintain a bloodless operative field. An inflatable pneumatic cuff is placed around the limb, 10 to 15 cm proximal to the surgical site, prior to preparing and draping the surgical site. If the cuff is applied proximal to the carpus or the tarsus, a gauze roll is placed on the medial and lateral sides of the limb over large vessels underneath the tourniquet to facilitate blood flow occlusion. A long latex rubber bandage is tightly wrapped around the limb to force the blood from the limb, starting over the hoof and proceeding in a proximal direction. Once the Esmarch bandage reaches the pneumatic tourniquet, the cuff is inflated above systolic pressure to occlude blood flow into the limb (approximately 600 mm Hg) (see Fig. 13-15). Subsequently, the Esmarch is removed. Nonpigmented skin will appear blanched. The tourniquet is generally left on the limb for no longer than 2 hours.

Thermal Hemostasis

Electrocoagulation is a commonly used method of hemostasis. Heat generated from high-frequency alternating electrical current traveling between two electrodes causes protein denaturation inside tissue cells. Tissue damage from heat production occurs between 3000 and 4000 Hz. Electrosurgical units can generate currents ranging between 1.5 and 7.5 MHz, and if too high a current is applied, the intracellular fluid boils instantly, potentially causing the vessel to explode without achieving coagulation.

Electrosurgical units can produce different types of currents. A partially rectified waveform achieves the most effective hemostasis. Vessels up to 2 mm in diameter can be coagulated in two ways. Obliterative coagulation is performed by direct contact between the hand-held electrode and the vessel. This causes the vessel wall to shrink, occluding the lumen by thrombus and coagulum formation. Alternatively, hemostasis can be achieved by coaptive coagulation. In this method, the vessel is initially occluded by a hemostatic forceps. The electrode of the electrosurgical unit then contacts an instrument that conducts the energy to the vessel, inducing permanent occlusion of the vessel. This technique allows precise electrocoagulation of a vessel.

Cryogenic hemostasis, as the name implies, is the rapid freezing of vessels to cause coagulation. The technique of cryosurgery is discussed in detail in Chapter 15.

Chemical Hemostasis

Occasionally, epinephrine is used to control hemorrhage. Epinephrine is a potent α-adrenergic agonist that causes peripheral vasoconstriction. A solution of 1:10,000 to 1:20,000 is used to control superficial bleeding of mucosal and subcutaneous tissues. Gauze packing soaked with a dilute epinephrine solution is an effective way to control bleeding.

Intravenous injection of 10% buffered formalin at a dosage of 0.02 to 0.06 mL/kg body weight diluted 1:9 in physiologic saline solution has been shown to be effective in controlling diffuse bleeding. The exact mechanism of action is unknown, but it may be the result of induction of coagulation on the endothelial cell surface. Close monitoring of the patient during application is recommended. This technique is applied to stop bleeding after castrations, colic surgeries, and surgical interventions of the upper airways.

Physical Hemostasis

Soluble sponge-type materials control hemorrhagic oozing by promoting clot formation. Various types of hemostatic materials include gelatin foam, oxidized cellulose, oxidized regenerated cellulose, and micronized collagen. While these materials transmit pressure against the wound surface, the material’s interstices provide a scaffold on which a clot can organize. These materials are most beneficial for low-pressure bleeding and in friable organs that cannot be readily sutured. The materials are nontoxic, but they will delay wound healing and can potentiate infection because they are absorbed by phagocytosis.

Figure 13-15. A, An Esmarch bandage (a) and pneumatic tourniquet (b) used for occluding blood flow in a limb. B, Application of an Esmarch bandage and a pneumatic tourniquet. Gauze rolls are placed over vascular pressure points under the tourniquet (arrow).
Bleeding from the bone can be controlled with the help of bone wax, which consists of purified and sterilized beeswax. The wax is physically packed onto the bone to block oozing of blood from cut cortical and cancellous bone. The material is relatively nonirritating, but it will remain in contact with the bone for years.7

TISSUE RETRACTION AND HANDLING

Retraction

Unnecessary tissue trauma induces inflammation, which can delay healing. Therefore, incisions should be made only as long as necessary to allow adequate exposure. Gentle manipulation of tissue with respect to blood supply, innervation, and hydration is essential for atraumatic surgical technique. To achieve this, instrument retraction may be preferred over direct hand retraction in selected situations.

Hand-held retractors are designed with a single handle and blade, to be used as an extension of the assistant’s hand. Alternatively, self-retaining retractors are designed with a locking mechanism on the handles to keep the blades in an open position. The blades of the retractor are placed within the incision and opened until the tissues on each side of the incision are spread maximally. Occasional repositioning or relaxation of the instrument blades, in conjunction with padding (i.e., moist gauze sponges placed between the blades of the retractor and tissue), minimizes tissue damage.

Careful retraction and stabilization of nerves and neurovascular bundles with Penrose drains or umbilical tape should always be considered in place of metallic retractors.12

Careful and atraumatic tissue handling is as important as applying aseptic technique during surgery. Rough handling of the tissues may induce inflammation and subsequent delayed wound healing.

Tissue Handling

An incision heals from side to side, not from end to end. Therefore, the incisions should be long enough to facilitate a clear view of the surgical site. Inadequate exposure may lead to increased tension on the tissues through overzealous retraction, jeopardize hemostasis, and increase the risk of traumatizing a nerve or vessel.

Sharp dissection should be carried out with sharp instruments. The use of dull scalpel blades, and dull and worn-out scissors only increases tissue trauma. Whenever possible, natural tissue cleavage planes should be followed during dissection; this prevents inadvertent transection of or tearing of fibrous tissues that heal poorly, if at all. Excessive undermining of tissues should be avoided, because it leads to the formation of dead spaces, which allow hematoma and seroma formation.

Most tissues should be handled with appropriate instruments; fingers should not be used. In small wounds, the introduction of a surgeon’s finger prevents adequate evaluation of the deeper structures. Probing with a thin instrument allows simultaneous observation and manipulation. Tissue forceps are available for just about any manipulation necessary. Applying hemostatic forceps to tissues not intended to be excised should be avoided, because the tissues are crushed and devitalized. Allis forceps are designed to hold tissues. However, excessive compression of the tissues in the clamp should be avoided. Stabilization and retraction of tissue may be accomplished in a variety of ways besides by using tissue forceps. In selected situations, the assistant’s fingers may accomplish effective atraumatic temporary occlusion of bowel to facilitate an enterotomy. Alternatively, a pair of self-retaining Doyen clamps may serve the same purpose.

Stay sutures can be used in a variety of situations—for example, to stabilize vessels and bowel. These sutures can be placed through very small amounts of tissue and still allow manipulations without pulling out. Hand-held and self-retaining retractors can be used in many surgical procedures to help facilitate certain manipulations.

Nerves and vital vessels should be spared whenever possible. Once they are isolated, they should be manipulated with great care. The identification of these structures with the help of a Penrose drain is atraumatic and effective.

SURGICAL IRRIGATION AND SUCTION

Surgical Irrigation

Operative wound lavage has been associated with reduced rates of postoperative infection for both clean and contaminated wounds in direct proportion to the volume of irrigation solution used.16,17 This phenomenon has been attributed to the removal of surface bacteria and debris from contaminated wounds, dislodgement and removal of bacteria and exudate from infected wounds, and dilution and removal of toxins associated with infection.17 An additional benefit of wound lavage and suction is the moistening of tissues to counteract the dehydrating effects of air and surgical lights. Wound lavage removes blood from the surgical site, which also improves visibility. Various types of lavage solutions, delivery systems, and suction devices have been developed, depending on where they are applied (e.g., body cavity, skin), the type of wound (e.g., traumatic, surgical), and the presence or absence of contamination or infection.

The ideal lavage solution is sterile, nontoxic, isoosmotic, and normothermic.18 Sterile 0.9% physiologic saline, lactated Ringer’s solution, and Plasmalyte are examples of available solutions that approach these criteria. Antibiotics are often added to a lavage solution as prophylaxis against possible infection, or if contamination has occurred. Even though some effect has been reported,19 conclusive evidence that this technique is superior to saline lavage alone is lacking.7 Infection implies bacterial penetration of tissues, and adequate blood and tissue concentrations of antibiotics via systemic administration are required for effective bacterial destruction.7 Some antibiotics, such as tetracycline, are irritating when applied to exposed tissue or peritoneal surfaces and should be avoided.19 Antiseptics such as povidone-iodine and chlorhexidine may be added to lavage solutions.

Fluid delivery systems used for irrigation vary depending on the area being irrigated and the presence or absence of contamination or infection. Lavage of body cavities is accomplished by flooding the cavity with large volumes of sterile solution, followed by suctioning to remove the fluid. This is usually performed by pouring the sterile solution from the bottle or a bowl into the cavity, or with a system capable of delivering large volumes of fluid at low pressure (referred to as diuresis).
Alternatively, traumatic and surgical wounds of the limbs are usually lavaged with the solutions under pressure. This is especially important if contamination or infection is present, because it dislodges bacteria or debris. A bulb syringe or a 60-cc dose syringe is adequate for keeping tissues moist and removing débrided tissue particles in some circumstances, but automated systems that deliver a high volume of lavage solution at pressures not exceeding 10 to 15 pounds per square inch should be used on heavily contaminated tissues (additional information on wound lavage techniques can be found in Chapter 26).

**Suction**

Suctioning efficiently removes blood and fluid from the surgical site. A suction tip attached to sterile tubing connected to a suction pump that delivers a vacuum of 80 to 120 mm Hg is recommended (Fig. 13-16). When gentle suction is indicated, such as in deep incisions where exposure is limited, a Frazier tip is used. This tip has a side-hole port near the handle, which can be used to vary the amount of suction force by either leaving the port uncovered or covering it with the index finger. When suctioning a large volume of fluid a Yankauer suction tip with a single port tip can be used. The multifenestrated sump-type design of the Poole tip makes it ideal for use in body cavities, where a single-port tip will plug or injure viscera. Figure 12-16 in the preceding chapter shows these special tips.

**CURETTAGE**

Curettage refers to the removal of a growth or other tissue from the wall of a cavity or other surface with a curet. Curettage can be used in all types of surgical interventions, but it is mainly applied in orthopedic procedures. Débridement of sequestra, excess bone production such as periosteal exostoses, damaged or diseased articular cartilage, and subchondral bone during an articular procedure (arthroscopy or arthrotomy) represent some surgical procedures that may involve curettage. It can also be used to remove necrotic soft tissue and debris from wounds, such as the tissue covering the bone after removal of a bone plate. The curet is used in an axial rotational motion (utilizing its cuplike design at the instrument tip) to scoop out tissue, or with a pulling motion to scrape tissue from the surgical site. The handle of the instrument is grasped in the palm of the dominant hand and the index finger is placed on the shaft of the instrument to help stabilize the tip against the tissue (Fig. 13-17).

CHAPTER 14

Minimally Invasive Surgical Techniques

Andrew T. Fischer, Jr.
Joanne Hardy
Renée Léveillé
Astrid B.M. Rijkenhuizen
Jörg A. Auer

The evolution of minimally invasive human surgery that peaked in the 1980s has been matched by a parallel development in minimally invasive surgical techniques in the horse. The evaluation of joints by arthrotomy, which was common until the mid 1980s, has been replaced by arthroscopy for almost all indications. Laparoscopic surgical techniques have continued to replace previous open techniques such as cryptorchidectomy, ovariohysterectomy, and inguinal hernia repair. In some cases, new techniques have been developed that were not previously available in the horse (e.g., testiclesparing mesh repair of the inguinal ring). Thoracoscopic techniques are also continuing to evolve but at a slower pace because of the infrequency of surgical disease of the equine thorax. The three major applications of rigid endoscopy (laparoscopy, arthroscopy, and thoracoscopy) share common surgical techniques and basic equipment. This chapter describes specialized equipment unique to each application.

Embolization and thrombectomy techniques can be conducted through catheters introduced into vessels. These procedures are effective techniques for treating disorders that a few years ago could be attempted only with great risk to the patient.

Computer-assisted surgery has only recently been introduced into equine surgery and may play a major role in orthopedic surgery of the future.

In addition to smaller surgical incisions, minimally invasive surgical techniques are characterized by vastly improved visualization. This has led to improved surgical outcomes and better overall understanding of regional anatomy. Minimally invasive techniques continue to evolve and replace previous open techniques as more surgeons become comfortable with them and as more thought is devoted to their development.

ENDOSCOPY

Equipment

Illumination

Most minimally invasive procedures require a means of getting illumination into the body cavity and a telescope with which to view the target organs. The supply of light into the patient’s body cavity was a limiting factor until the development of cold light sources, which allowed high-intensity illumination of the cavity without danger to the patient or surgeon from excessive heat. The next major limitation of early arthroscopy and laparoscopy was the lack of video imaging equipment, which prevented an assistant from participating in the surgery. The inability to be aided by an assistant limited the procedures to those that could be accomplished with one hand. Beam splitters were developed to share the image on the surgical telescope, but they were unwieldy and they markedly decreased the amount of light, resulting in a poor image. As video cameras were developed and refined, arthroscopy, laparoscopy, and thoracoscopy

In addition to smaller surgical incisions, minimally invasive surgical techniques are characterized by vastly improved visualization. This has led to improved surgical outcomes and better overall understanding of regional anatomy. Minimally invasive techniques continue to evolve and replace previous open techniques as more surgeons become comfortable with them and as more thought is devoted to their development.

ENDOSCOPY
Equipment
Illumination
Most minimally invasive procedures require a means of getting illumination into the body cavity and a telescope with which to view the target organs. The supply of light into the patient’s body cavity was a limiting factor until the development of cold light sources, which allowed high-intensity illumination of the cavity without danger to the patient or surgeon from excessive heat. The next major limitation of early arthroscopy and laparoscopy was the lack of video imaging equipment, which prevented an assistant from participating in the surgery. The inability to be aided by an assistant limited the procedures to those that could be accomplished with one hand. Beam splitters were developed to share the image on the surgical telescope, but they were unwieldy and they markedly decreased the amount of light, resulting in a poor image. As video cameras were developed and refined, arthroscopy, laparoscopy, and thoracoscopy...
became popular. With time, the complexity of procedures markedly increased, as did the number of surgeons performing them.

Currently, light sources are capable of providing intense illumination to the selected cavity (Fig. 14-1). Most manufacturers produce light sources with 300 watts of output from xenon bulbs. Xenon light sources are preferred, as they offer more lumens per watt than halogen light sources, and the light is whiter, offering more accurate reproduction of colors. A flexible fiberoptic or liquid light cable is needed to transmit the light from the light source to the telescope. Light cables are available in many lengths, but a 10-foot-long cable is generally preferred for equine endoscopy. A fiberoptic light cable must be checked regularly for broken fibers and must be well maintained by thorough cleaning. Poor illumination of the cavity can frequently be traced to a light cable with many broken bundles. However, a liquid light cable does not have this problem. Although a bit more expensive, they are quite durable and not subject to fiber bundle breakage.

When the light source is on and the light cable is connected to the light source, it is important that the distal end of the light cable or the telescope not be left in contact with the patient, drapes, or any other combustible material, as burns may occur or fires may start as a result of the heat produced at the tip.

The three areas of rigid endoscopy all use a trocar and cannula assembly to first enter the body cavity (Fig. 14-2). The cannula protects the telescope after insertion and has stopcocks allowing fluid infusion or gas insufflation for distending the cavity. The cannula has seals to prevent leakage of fluid or gas through it.

**Telescopes**

A high-quality surgical telescope is very important for all endoscopic procedures (Fig. 14-3). The Hopkins rod lens system provides more light transmission for illumination of the cavity and a wider field of view than traditional optical systems. Light is provided by optical fibers that surround the lens system. Telescopes of 5 mm or less in diameter provide adequate light and visualization for arthroscopy but not for laparoscopy or thoracoscopy. The reasons for this are that the cartilage covering the articular surfaces of the bones in the joints is bright and reflective, and the cavity is smaller. The most common telescope size used in equine laparoscopy and thoracoscopy has a 10-mm outside diameter. The large size allows adequate light transmission with good visualization. The standard length for arthroscopes is 15 to 25 cm with an extra-long 4-mm diameter arthroscope of 35 cm. The standard length for human laparoscopes is approximately 30 cm, but a specially designed 57-cm laparoscope is available for equine use. The distal ends of endoscopes are designed with different lens angles. The most commonly available distal angles are 0, 25, or 30 degrees of visualization. The zero-degree telescope allows more light transmission into the body cavity but does not offer the panoramic view that the 30-degree telescope provides. The 30-degree telescope allows panoramic visualization (which facilitates triangulation techniques), accomplished by rotating the scope (not possible with the zero-degree telescope). For special procedures, a 70-degree arthroscope is available, but it is rarely used.

**Video Equipment**

A video camera that connects to the telescope is necessary to ensure aseptic surgical technique and allow assistance during surgery. Most cameras contain either one chip or three chips—the charged capacitance devices (CCDs) used in the camera. Three-chip cameras have one chip for each of the primary colors (red, green, and blue) and generally offer better resolution than single-chip cameras. Newer video cameras have an increased light sensitivity, which is very helpful for laparoscopy and thoracoscopy in horses. Zoom features, gain changes, and multimedia image capture may also be offered as options on the various cameras. The video camera should be connected to a good-quality monitor in

![Figure 14-1. Basic equipment set up for minimally invasive surgery consisting of light source, light cable, video camera with camera processor, and monitor.](image-url)
the direct line of sight of the surgeon. In some cases, it is helpful to have multiple monitors for the benefit of the assistant surgeon. The choice of cable connections affects monitor image—S-video cables offer the highest resolution. Multimedia digital capture of video-assisted surgery is becoming standard procedure and can be accomplished through the use of personal computers, stand-alone video documentation systems, or video recorders incorporating hard disk storage and DVD burners.

**Fluids and Gases**

Arthroscopic, laparoscopic, and thoracoscopic procedures all require the creation of an optical cavity. The optical cavity allows separation of the joint capsule or body wall from the contents of the cavity, which facilitates a thorough visual exploration.

Adequate visualization during arthroscopy is accomplished by the use of fluid or gas distention of the joint. Fluids used for joint distention are pH-balanced polyionic solutions such as lactated Ringer’s solution. If electrosurgical instrumentation within the joint is going to be used, specially devised fluids suitable for this are needed. Fluid distention is usually obtained by the use of pressure or manually controlled pumps, but it can also be achieved by gravity. Excessive fluid pressure is associated with extravasation of the fluid, resulting in marked subcutaneous edema and poor visualization because pressure on the skin and subcutaneous tissues compresses the joint capsule. Arthroscopy using gas insufflation may be used when the joint surfaces must remain dry (e.g., in insertion of cartilage grafts). The pictures obtained with gas insufflation are clearer and truer to actual intra-articular colors. The insufflation technique is identical to the one described later for laparoscopy.

The abdominal cavity requires insufflation for optimal viewing. Insufflation is accomplished by insufflators that provide a controlled flow of gas into the patient’s cavity. Settings on the insufflator should be available that limit flow rate and pressure in the cavity to be examined. Insufflators for equine use should have flow rates that can...
exceed 10 L/min, and 20 L/min is desirable. Slower-rate insufflators require too long a time for adequate insufflation to occur or for the cavity to be reinflated if it becomes deflated. Initially, the rate of flow of gas into the patient is limited by the smallest diameter in the circuit, which is typically the insufflation needle. Needles such as the Verres needle have flow rates of less than 3 L/min, whereas teat cannulas can accomplish flows of 6 to 7 L/min. Once the laparoscopic trocar is inserted, the limit on flow rate is usually the insufflator.

The most commonly used gas for insufflation is carbon dioxide. Other inert gases have also been used in human medicine. The patient’s abdominal pressure is usually 15 mm Hg or less. Higher pressures are associated with increased patient discomfort and respiratory compromise and are not necessary for visualization. Insufflation is less commonly used in thoracoscopy because of the tendency for the lung to collapse when air is allowed to enter the thorax passively. When insufflation is necessary during thoracoscopy, 5 mm Hg is usually adequate. The use of high intrapleural pressures is unnecessary; high pressure decreases cardiac return and interferes with ventilation. Selective bronchial intubation may be performed for thoracoscopy in cases requiring general anesthesia.

**Surgical Instruments**

The basic instruments necessary for arthroscopy include probes, rongeurs, grasping forceps, chisels, mallet, curets, periosteal elevator, flush cannula, and a bone awl. Probes are used to evaluate looseness of fragments, determine stability of cartilage, and manipulate structures, testing their integrity or improving visualization (Fig. 14-4). Multiple rongeurs may be used in a single surgery, and the choice is dictated by the operative target. Ferris-Smith rongeurs are available in different sizes and with different jaw angles (straight, angled up, and angled down), and an assortment should be available in each surgical pack (Fig. 14-5). Grasping forceps are used to remove fragments from the joint (Fig. 14-6). Grasping forceps with small teeth in the jaws are better at grasping than rongeurs. Chisels, osteotomes, and
periosteal elevators are used to elevate osteochondral fragments with or without the use of a mallet. Curets are used to debride cartilage edges and remove devitalized bone. Several different sizes and angles should be available to maximize access to the base of the defect. Bone awls are used to produce microfractures in the subchondral bone plate, which are thought to improve cartilage adhesion after bone débridement of the articular surface (see Chapter 84). Flush cannulas are useful for lavaging the joint and removing any remaining bits of cartilage or bony debris (Fig. 14-7). Motorized equipment is useful for synovectomy, meniscectomy, tendon débridement, and removal of cartilage flaps. Different blades are used according to the structure being débrided.

The basic instruments used for laparoscopy include probes, Semm claw forceps, scissors, Babcock forceps, and biopsy forceps. Probes are used to probe organs and provide tactile feedback regarding the consistency of the target, and to evaluate organ attachments. Semm claw forceps provide good security when grasping tissue that is to be removed from the patient (Fig. 14-8). Atraumatic forceps such as Babcock forceps allow tissue manipulation without injury and are useful in exploratory laparoscopy or thoracoscopy (Fig. 14-9). Endoscopic scissors are used for dividing tissue after adequate hemostasis has been obtained (Fig. 14-10). Biopsy forceps are used for visceral biopsy (spleen, kidney, liver, and other solid organs) or tumors. Hemostatic devices such as endoscopic staplers, electrosurgical units, ultrasonic scalpels, and different types of lasers are routinely used and will be discussed in appropriate chapters.

**Triangulation Technique**

Arthroscopic, laparoscopic, and thoracoscopic surgical procedures all share the common technique of triangulation. Triangulation refers to the placing of telescope and instruments through separate portals so that they converge on the operative target. Mastering the technique of triangulation is essential to becoming competent in minimally invasive endoscopic techniques. The visual target should be in front of the surgeon, with the monitor directly behind the visual target. The camera must be kept in an orientation that maintains the true vertical and horizontal axes to facilitate proper movement of the surgical instruments toward the...
surgical target (Fig. 14-11). Triangulation techniques should be learned with training boxes before surgery is attempted on clinical cases. In general, the diagnostic evaluation in all minimally invasive surgeries should be performed before instrument portals are established, as they can collapse the optical cavity and interfere with visualization. An exception to this occurs when instrumentation must be introduced to manipulate viscera to facilitate exploration. Once the diagnostic exploration has been accomplished, additional instrument portals are established for the surgical procedure. The details for specific procedures are found in subsequent chapters and specialized texts.1-3

EMBOLIZATION
Arterial embolization refers to catheter-directed delivery of particulate material for the purpose of embolizing selected arteries. Currently, microcoils are the most popular embolization material. They have been used for occlusion of normal and abnormal vasculature, and for creating ischemia of neoplastic tissue (Fig. 14-12). In dogs, coil embolization has been used for vascular occlusion of patent ductus arteriosus,4-8 occlusion of portosystemic shunts,9-14 treatment of epistaxis,15 and experimental treatment of cerebral aneurysms.16 In horses, coil embolization has been used to occlude branches of the common carotid artery usually involved in guttural pouch mycosis.17-20 The use of emulsions for embolization of tumors for the purpose of creating ischemia and reducing tumor size has also been described.21 Chemoembolization refers to selective intra-arterial delivery of chemotherapeutic agents in conjunction with particulate material for the purpose of embolizing arteries supplying blood to a tumor.22 Numerous studies describe its use in humans and dogs, using various chemotherapeutic agents.23-27

Surgical Technique
Catheter-directed embolization involves accessing a peripheral artery, where an introducer is inserted. A catheter is then directed, under fluoroscopic guidance, within the artery until the tip of the catheter is located at the desired site of embolization. Accessing the proper site requires knowledge
of local vascular anatomy and variances within individuals. Navigation through the arterial tree is facilitated by using a gliding guide wire inserted within the catheter. Once the site of embolization is reached, the embolization material is delivered. The catheter and introducer are removed, and hemostasis at the arterial puncture site is achieved by direct pressure or suturing.

The sizes and materials used for embolization techniques are very specific, and correct selection of product characteristic for the desired purpose is essential. For example, catheters made of polyvinylchloride (PVC) or vinyl do not allow the coils to glide within the catheter, resulting in occlusion of the catheter. Similarly, selection of too small a coil diameter allows the coil to travel farther into the arterial vasculature, where it might embolize an undesired vessel. For details on use of this technique to control bleeding from guttural pouch mycosis, see Chapter 45.

**THROMBECTOMY**

Aortic-iliac thrombosis (TAI) in the horse is an unusual cause of hind limb lameness.28,29 Diagnosis is often difficult, and conservative treatment is usually unrewarding.28,29 Therefore, a surgical treatment has been explored. Thrombectomy via minimally invasive surgery has been used successfully for chronic arterial occlusive disease of the aorta and its caudal arteries.

The most common manifestation of TAI is a predictable exercise-induced lameness that ceases with a resting period of 5 to 10 minutes. Horses that are forced to train despite the lameness exhibit a more severe lameness and may require significantly more time for the symptoms to resolve. More severely affected horses take longer to recover. After physical activity, there is an absence of sweating, retarded venous vein filling, and hypothermia of the distal extremity of the affected limb. Initially, symptoms are exhibited only after exercise. As the disease progresses, clinical signs are also present at rest, because of ischemia in the hind limb.

TAI is progressive with a gradual onset. The clinical signs are determined by the degree of vascular occlusion, the presence of collateral circulation, and the speed of the onset of the occlusion.28-30 Affected horses can be asymptomatic or show only vague performance deficits. Occasionally, part of a thrombus dislodges from a proximal location and acutely occludes a distal peripheral artery. After training, acute colic-like signs may occur (pawing, straining, sweating, lying down and rolling), mostly combined with a severe lameness.

Diagnosis is based on history, clinical presentation, and rectal palpation, in combination with ultrasonography, thermography (if available), and scintigraphy.31-38 Information on the onset of ischemic symptoms, the duration of symptoms, the characteristics of pain, and any alleviating factors is helpful. The absence of a pulse in an extremity is probably the most common physical finding. Rectal ultrasonography is used to recognize the thrombus in the aorta and the internal and external iliac artery. Doppler ultrasonography renders both an anatomic and a functional assessment of the femoral artery in the inguinal region. This technique is also used to estimate the degree of arterial occlusion.39 The femoral artery is visualized in the femoral triangle (trigonum femorale), which is bordered caudally by the pectineus and cranially by the sartorius muscles, over a distance of approximately 15 cm. In unilateral cases, the unaffected hind limb can be used as a reference.

To monitor the development of hypoxemia in the affected hind limb, the oxygen pressure in venous blood samples before and after a workload can be measured.33 The samples are taken from the right and left saphenous veins as far proximally as possible—that is, at the level of the stifle joint. Samples are collected anaerobically in heparinized 2-ml syringes, which are immediately sealed so that they are airtight, and then immersed in ice. Within 15 minutes after the first sample is taken, they are tested in a blood gas analyzer.

Conservative treatment with exercise programs and pharmacologic therapy with sodium gluconate, with or without fibrinolytic enzymes, anticoagulants, and vasodilators, has thus far been unsatisfactory.4 Promising results were seen in unilaterally affected horses by restoring blood supply to the ischemic regions through thrombectomy with the use of a Fogarty graft thrombectomy catheter.35

**Surgical Technique**

The horse is anesthetized and positioned on the surgery table in lateral recumbency with the affected limb down. The upper hind limb is secured in flexion and abduction. An approximately 10-cm-long incision is made medially over the saphenous vein where its course changes from superficial to deep (Fig. 14-13). Dissection of the vein is continued as it courses proximally, until the femoral artery is identified. The femoral artery is carefully isolated and stabilized with two large sutures, and two vascular clamps (aortic forceps, DeBakey-Morris) are placed proximally and distally to prevent excessive blood loss during surgery. Small arterial branches of the femoral artery are ligated if this is necessary to gain exposure.

A transverse arteriotomy is performed and the blood flow is observed by loosen ing the clamp and removing the proximal suture. Visible thrombi are loosened from the arterial

*References 29, 30, 34, 35, 37, 40.

Figure 14-13. Intraoperative view of the saphenous vein. The femoral artery is located by following the saphenous vein proximally.
wall and removed with forceps (Fig. 14-14). Subsequently, the Fogarty catheter (50 cm long, with a closed diameter of 4 mm and an expanded diameter of 16 mm) is inserted in collapsed form into the femoral artery, directed proximally, and positioned beyond the saddle thrombus. The catheter has a flexible wire coil at the distal end that expands when retracted to form a double-helix ring (Fig. 14-15). The sliding knob on the handle of the catheter is retracted slowly, which causes the wire loops to partially expand and move the thrombi distally as the catheter is withdrawn. This procedure is repeated with the diameter of the coil more expanded until no resistance is felt during withdrawal of the catheter, and no more thrombi are retrieved (Fig. 14-16). By removing this blockage, blood flow is restored from the proximal side. When indicated, additional thrombectomies are performed distal to the incision. Before closure of the artery, blood is allowed to flow freely with the distal clamp closed for a short period to remove any detached thrombi and air. Prior to reclamping the artery for closure, 20 mL of a heparin solution (250 IU heparin/mL physiologic saline solution) is injected into the femoral artery, in both a distal and a proximal direction. The incision in the femoral artery is sutured using a simple continuous suture pattern of monofilament polypropylene (5-0). Fascia and subcutis are closed with a simple continuous suture pattern, followed by skin closure using an intradermal continuous suture.

Anticoagulation is obtained intra-operatively just before arteriotomy by the intravenous administration of 100 IU heparin/kg. This is followed postoperatively by the subcutaneous administration of 50 IU heparin/kg twice daily for 2 days, and carbasalatum calcium 5 mg/kg (Ascal, Dagra Pharma) orally once daily for at least 3 months. Hand walking is advised immediately after surgery, after which light exercise can begin.

A severe complication is the appearance of TAI in the contralateral limb after surgery because of thromboembolization caused by dislodged clot fragments. Postanesthetic myopathy is seen in 60% of the cases and assumed to be caused by local hypoxemia of various muscle groups. Horses with TAI that have preexisting hypoxemia before surgery are therefore at high risk for this complication. Adequate padding, correct positioning, prevention of intraoperative hypotension, and keeping surgery time as short as possible are important considerations.

The prognosis after surgical intervention is reasonable, with a 50% return to athletic function.
COMPUTER-ASSISTED SURGERY

Internal fixation of fractures is usually planned on the basis of a radiographic study. Occasionally, computed tomography (CT) is used to determine the exact course of the fracture line as it courses along the bone. Such a study allows the surgeon to determine exactly where to implant screws. Nevertheless, the actual result depends greatly on the surgeon’s skill to insert the implants according to the preoperative plan. Computer-assisted surgery (CAS) allows the surgeon to accurately implement the preoperative plan and to implant screws at the desired location and at the correct angle relative to the fracture plane.41

Surgical Technique

The equipment used at the Equine Hospital of the University of Zurich, Switzerland, is composed of instruments equipped with infrared light-emitting diodes (LEDs), the Medivision SurgiGate (Praxim-Medivision, Inc, Grenoble, France) navigation system, and the Siemens Siremobil Iso 3D C-arm (Siemens AG, Munich, Germany) (Fig. 14-17). These instruments together define the fractured bone in three dimensions and allow real-time observation of the actual implantation of the screw in three planes simultaneously.41

First, the dynamic reference base (DRB) is securely attached to a Schanz screw, which was previously attached to the fractured bone. Subsequently, the fractured bone is isocentrically positioned between the two components of the C-arm. Positioning is assisted by two laser beams positioned at 90 degrees relative to each other. Special attention is given to allow movement of the C-arm over a 190-degree arc without interfering with any object (e.g., the surgery table). The C-arm and the DRB must be located in the identifiable view of the navigation camera. Over a 2-minute period, the C-arm takes 100 still radiographs over an arc of 190 degrees, which are processed into 256 single pictures and sent to the SurgiGate computer. The radiographic images can be viewed in three planes that are oriented at right angles to each other (in the horizontal, parasagittal, and frontal planes).

The SurgiGate system consists of a navigation camera, a computer unit with sophisticated 3-dimensional software, the instruments (e.g., a power drill and an awl), and a virtual keyboard that allows the surgeon to navigate within the system and calibrate the instruments under aseptic conditions during surgery (Figs. 14-17 and 14-18). The data collected with the Siremobil Iso 3D is subsequently transferred to the SurgiGate computer, where the future location of each screw is planned on the screen and marked. The SurgiGate system is then changed to real time to guide the surgeon during the actual implantation. This is carried out by observation of the computer screen and matching the drill and subsequently needed instruments with the planned image in three planes, similar to an arthroscopic technique (Fig. 14-19). Once the location is matched, drilling is initiated. As soon as the drill bit crosses the fracture plane, which can be seen on the screen, the drill bit is changed to prepare the thread hole (Fig. 14-20). Insertion is then routine.
Three-dimensional navigation systems such as the Medivision SurgiGate in combination with the Siremobil Iso 3D has great potential to be a real advantage for the precise and accurate implantation of lag screws in fractures in the horse. It has been used successfully in a limited number of clinical cases. A controlled study on cadaveric limbs is underway to evaluate the value of the system.\textsuperscript{12} Potential future indications for CAS include fractures of the distal, middle, and proximal phalanx, condylar and saucer fractures of MCIII and MTIII, and cystic lesions of the various bones. A study is presently being conducted on the use of CAS in the management of navicular bone fractures.

REFERENCES

20° C (temperature of −4° F). Primary injury begins with the formation of ice crystals, both intracellular and extracellular. The cell’s outer membrane becomes ruptured by intracellular crystals, and ice formation outside the cell dehydrates the cellular environment, resulting in lethal electrolyte concentration and pH changes. When organelles are damaged, the cell loses its ability to regulate ion permeability, and cell death ensues. Secondary injury from freezing occurs from vascular stasis. As the permeability of vessels is increased, loss of plasma causes local hemoconcentration. Damaged endothelium in arterioles and venules induces thrombus formation of the vessels, and infarction of frozen tissue occurs within hours of freezing.

Rapid freezing results in the greatest intracellular concentration of ice. Thereafter, slow thawing of the tissue results in recrystallization, during which small crystals enlarge, producing more cell damage. To ensure that all target tissue receives a lethal dose of cold, a second freeze/thaw cycle is used. Because precooled tissue freezes faster than normal tissue, repeating this cycle causes necrosis of the target tissue more consistently.

Variations in vascularity, noncellular structure, and water content cause tissues to respond differently to cryonecrosis. Dry tissues (e.g., the cornea) do not readily form ice crystals and therefore do not respond to cryotherapy very well. The cellular components of peripheral nerves are destroyed by freezing, but because the fiber scaffolding of the epineurium is not damaged, regeneration is possible.2 Tissues near major blood vessels or in highly vascular areas are difficult to freeze rapidly and tend to thaw quickly without loss of function.3 The use of epinephrine or temporary regional vessel occlusion may be necessary to ensure proper treatment in those tissues.

Although immune responses directed against tumor cells have been documented after cryosurgery, this has not been proven clinically in horses.4 However, numerous case reports...

PRINCIPLES OF CRYOBIOLOGY

Mammalian cells are destroyed when cooled to a temperature of \(-20^\circ\text{C} (\sim 4^\circ\text{F})\). Primary injury begins with the formation of ice crystals, both intracellular and extracellular. The cell’s outer membrane becomes ruptured by intracellular crystals, and ice formation outside the cell dehydrates the cellular environment, resulting in lethal electrolyte concentrations and pH changes. When organelles are damaged, the cell loses its ability to regulate ion permeability, and cell death ensues. Secondary injury from freezing occurs from vascular stasis. As the permeability of vessels is increased, loss of plasma causes local hemoconcentration. Damaged endothelium in arterioles and venules induces thrombus formation of the vessels, and infarction of frozen tissue occurs within hours of freezing.

Rapid freezing results in the greatest intracellular concentration of ice. Thereafter, slow thawing of the tissue results in recrystallization, during which small crystals enlarge, producing more cell damage. To ensure that all target tissue receives a lethal dose of cold, a second freeze/thaw cycle is used. Because precooled tissue freezes faster than normal tissue, repeating this cycle causes necrosis of the target tissue more consistently.

Variations in vascularity, noncellular structure, and water content cause tissues to respond differently to cryonecrosis. Dry tissues (e.g., the cornea) do not readily form ice crystals and therefore do not respond to cryotherapy very well. The cellular components of peripheral nerves are destroyed by freezing, but because the fiber scaffolding of the epineurium is not damaged, regeneration is possible. Tissues near major blood vessels or in highly vascular areas are difficult to freeze rapidly and tend to thaw quickly without loss of function. The use of epinephrine or temporary regional vessel occlusion may be necessary to ensure proper treatment in those tissues.

Although immune responses directed against tumor cells have been documented after cryosurgery, this has not been proven clinically in horses. However, numerous case reports...
suggest secondary tumor regression does occur as a result of cryosurgical treatment of a primary tumor.\textsuperscript{5,6}

Although liquid nitrogen, nitrous oxide, and carbon dioxide are all cryogens used in veterinary medicine, liquid nitrogen is the most versatile and therefore the most commonly used. Liquid nitrogen has a boiling point of $-195.8^\circ \text{C}$ ($-320.4^\circ \text{F}$). Cryogens, usually stored in liquid form in Dewar flasks (Fig. 15-1), can be delivered as a spray or used by super-chilling a probe. Two types of probes are used: hollow probes and solid probes. When hollow probes are used, liquid is circulated through the probe and exits under pressure through a small opening. When solid probes are used, they are chilled by immersion into the liquid cryogen.

**Indications**

Cryosurgery does not require a sterile field. Therefore, it is a good choice for the treatment of benign and neoplastic cutaneous lesions. It can also be used in the mouth and in ocular surgery. By far the most common tumor that is treated with cryotherapy is the equine sarcoid. However, a plethora of skin conditions amenable to surgery can be treated by cryotherapy (see Chapter 29). Because there is frequently no need for general anesthesia of horses afflicted with skin lesions, cryosurgery has an advantage over other types of surgical extirpations—it frequently can be done on an outpatient basis.

**INSTRUMENTATION**

**Sprays**

Self-pressurizing spray guns (Fig. 15-2) deliver a combination of vapor and droplets of liquid cryogen and are a most effective method of cryogen delivery. As liquid nitrogen contacts the tissue, it evaporates, or changes from the liquid to the gas phase. This has been shown to remove a greater amount of heat from treated tissue than is achieved with probes. The volume and size of the spray droplet are controlled by the diameter of the needle orifice (Fig. 15-3) and the trigger in the pressurizing gun. The surgeon can gauge the volume of the cryogen so that the wetting conforms to the shape of the tumor’s surface. However, care must be taken to prevent excess liquid cryogen from running off onto surrounding skin. It is common to pack the surrounding area with Vaseline-impregnated sponges to prevent this runoff. Alternatively, a spray cup (Fig. 15-4) can be used that has the advantage of controlling runoff. A cup size (Fig. 15-5) is chosen that fits over the tumor, and as the spray is applied, droplets form a liquid pool over the tumor.

**Probes**

Hollow probes are cooled by circulating a liquid cryogen through them. Hollow probe freezing is easiest to control, but the rate it cools an area is slow compared with the rate achieved by spray and solid probes. Hollow probes can be
used for either contact or penetration freezing, depending on the configuration of the probe (Fig. 15-6). During freezing, traction can be used to lift the tumor away from underlying structures as an ice ball is extended to the monitored limits. Penetration freezing can be performed in larger lesions where a core biopsy specimen is removed from the center of the tumor (Fig. 15-7) and the cryoprobe is placed within the mass. Contact freezing with solid probes is a very efficient manner of delivering cryotherapy to variously sized tumors, based on the size of the probe (Fig. 15-8). As multiple probes are placed within the liquid nitrogen (Fig. 15-9), they can be removed and used to freeze tumors quite rapidly—a large advantage when multiple tumors need to be frozen in the same patient.

CRYOSURGERY TECHNIQUES

Using either contact or penetration cryotherapy, monitoring the depth of freezing can be done either by subjective inspection or by objective measurement of temperature changes. Subjective assessment is made by visual inspection or palpation of the ice ball. The outer edge of the ice ball is about 0°C (32°F), which is inadequate for tissue destruction. Seventy-five percent of the tissue within an ice ball is destroyed by freezing. The depth of contact freezing is estimated to be slightly less than the radius of the ice ball. Pyrometers are used to measure the temperature achieved beyond the limits of the target tissue. Single- or multiple-channel monitors are available (see Fig. 15-2). Needle probes are placed into the tissue adjacent to the deepest portion of the target. When temperatures of −20°C (−4°F) are recorded, all unwanted tissue is destroyed.

COMPLICATIONS

Normal biologic reactions to freezing include swelling, bleeding, necrosis, depigmentation, and odor of varying degrees. Swelling occurs within hours of freezing because of increased vascular permeability and vasodilation. This is usually self-limiting and resolves in 48 hours. When lesions are biopsied or ulcerated and undergo cryotherapy,
Hollow probes come in a variety of shapes and can be used for either contact or penetration freezing.

Core biopsy instruments used to remove the center of a tumor so that the same size of hollow spray probe can be inserted into the center of the tumor to perform penetration freezing.

Solid probes come in a variety of sizes, each fitted with a separate plastic handle that does not become chilled as the probe is immersed in liquid nitrogen. Various sizes and shapes allow these probes to become a heat sink when pressed onto the surface of the tumor.

A special container is used into which liquid nitrogen is poured and the contact probe is submersed to attain the proper temperature before applying to a tumor.
Lasers in Veterinary Surgery
Lloyd P. Tate, Jr.

As technology and specialized instrumentation have expanded the realm of minimally invasive surgical procedures, public and veterinary awareness has greatly increased. Surgeries using lasers are minimally invasive in that they often do not require general anesthesia or an external incision, and they can be performed transendoscopically. The word laser is an acronym for light amplification by stimulated emission of radiation. Surgical lasers offer veterinarians the potential for expanding their surgical capability, decreasing complications, and improving patient care. To meet these goals and to avoid foreseeable complications, surgeons should understand laser–tissue interactions and the requirements for safe operation of surgical lasers.

FUNCTION OF THE LASER
Laser Physics
Energy is emitted by a laser in the form of light, called a photon. Understanding the emission process is an important first step toward applying the laser surgically. Light is characterized or defined by its frequency, wavelength, amplitude, and velocity. Numeric values given to these characteristics depend on the source from which the light is generated. A large number of medical lasers use the near-infrared spectrum. Examples of laser sources include carbon dioxide, argon, neodymium, gallium, and holmium. Each source is referred to as a laser medium (Table 16-1). All photons produced by a given medium have identical wavelengths and frequencies (frequency here is called coherence). The medium may exist in one of three forms: as a gas, a crystal, or a liquid. The medium requires an external energy source to produce the photon cascade that results in a laser beam.

The process of energizing a medium involves stimulating electrons and is referred to as pumping. Pumping may occur in several forms, such as heat, light, electricity, or even another laser beam. The pumping process does not determine the characteristics of photons produced by the medium; it is only a method of energizing the medium.

The medium and pumping source are two primary components of the laser. A third component is composed of two reflecting surfaces, one containing a shutter or semitransparent area. The reflecting surfaces are mirrors placed at either end of the medium. The mirrors and medium are contained within a resonating chamber (Fig. 16-1). Photons initially emitted by the medium are continually reflected back into the medium. As pumping continues, electrons from the medium are raised to a highly excited state. The electrons eventually gain sufficient energy to penetrate the semitransparent reflective mirror surface and exit as a laser beam.

Diode lasers do not require a resonating chamber, as they are fashioned from semiconductors and are referred to as solid-state lasers. Diode laser semiconductors are fashioned from gallium salts or more complex compounds. Functionally, semiconductors are made of two materials that vary in their ability to allow electrons to pass through them. At the interface or junction between two types of semiconductors,

CHAPTER 16

FUNCTION OF THE LASER

Laser Physics

Energy is emitted by a laser in the form of light, called a photon. Understanding the emission process is an important first step toward applying the laser surgically. Light is characterized or defined by its frequency, wavelength, amplitude, and velocity. Numeric values given to these characteristics depend on the source from which the light is generated. A large number of medical lasers use the near-infrared spectrum. Examples of laser sources include carbon dioxide, argon, neodymium, gallium, and holmium. Each source is referred to as a laser medium (Table 16-1). All photons produced by a given medium have identical wavelengths and frequencies (frequency here is called coherence). The medium may exist in one of three forms: as a gas, a crystal, or a liquid. The medium requires an external energy source to produce the photon cascade that results in a laser beam.

The process of energizing a medium involves stimulating electrons and is referred to as pumping. Pumping may occur in several forms, such as heat, light, electricity, or even another laser beam. The pumping process does not determine the characteristics of photons produced by the medium; it is only a method of energizing the medium.

The medium and pumping source are two primary components of the laser. A third component is composed of two reflecting surfaces, one containing a shutter or semitransparent area. The reflecting surfaces are mirrors placed at either end of the medium. The mirrors and medium are contained within a resonating chamber (Fig. 16-1). Photons initially emitted by the medium are continually reflected back into the medium. As pumping continues, electrons from the medium are raised to a highly excited state. The electrons eventually gain sufficient energy to penetrate the semitransparent reflective mirror surface and exit as a laser beam.

Diode lasers do not require a resonating chamber, as they are fashioned from semiconductors and are referred to as solid-state lasers. Diode laser semiconductors are fashioned from gallium salts or more complex compounds. Functionally, semiconductors are made of two materials that vary in their ability to allow electrons to pass through them. At the interface or junction between two types of semiconductors,
an electronic phenomenon occurs. When voltage is applied, electrons flow through the junction, causing a buildup of excited electrons on one side. When the system relaxes or current decreases, the electrons seek equilibrium by de-excitation, which causes an energy release in the form of an emitted photon (Fig. 16-2). The reason for the photon release is that pores present at the junction between the two semiconductors allow the electrons to travel through only when they are in a relaxed state. To return to a relaxed state, the energized electrons must release a photon. By channeling the photons from a series of diodes, the laser beam is produced. The materials used to construct semiconductors, the number of semiconductors used, and the voltage, current, and heat produced determine the frequency and power output of each laser. Large lasers using resonating chambers are being replaced by diode lasers, which have more efficient semiconductor cooling, allowing an increase in power output.

The laser beam is electromagnetic radiation or irradiation produced by stimulated emission from an excited medium or semiconductor. A unique characteristic of the laser beam is that it is spatially and temporally in phase, meaning that the photons are all of the same wavelength and traveling in parallel fashion. This characteristic of the beam is described as being collimated and monochromatic. Coherence, collimation, and monochromatic light are important parameters for transmission and focusing of laser irradiation. Lenses placed in the system control the beams, the focal length, and focal spot size. Focal spot size is referred to as the focal point, and its size determines the amount of energy delivered to an area of tissue. When laser energy is concentrated into a small focal point, it is used for cutting and vaporizing tissue. Divergence means that the focal point is either above or below the tissue surface. Thus, irradiation is less concentrated and requires more time at the same energy level to produce the same thermal effect. Divergent laser beams are often used for vessel coagulation.

Laser output power is expressed as watts, where delivered laser energy over time is expressed as watts per second (W/sec) or joules (J). Energy that is concentrated in a known area is called the power density and is expressed as a watt per square centimeter (W/cm²). Power density determines the type of biologic change that will be seen in tissue (Fig. 16-3). Laser energy applied over a large area of tissue has a diffuse thermal effect. A small focal spot concentrates the energy, producing deeper tissue penetration, which is preferred for making an incision. Thermal damage to tissue that is not immediately apparent is referred to as latent thermal necrosis. In resecting a tumor, it may be desirable to have latent thermal damage to achieve as much marginal destruction as possible. Latent thermal damage is best appreciated lateral to an incision line (Fig. 16-4). The type of laser, its medium, and how its irradiation is delivered and interacts with tissue influence the laser’s effectiveness as a surgical tool.

*The carbon dioxide and Nd:YAG lasers are popular for photoincision and ablation.
How a laser is used is influenced by how the beam and energy are delivered. A lens is often used at the delivery point to concentrate the laser beam, but with it, irradiation can be applied only in the direct line of sight. Attaching a transmitting fiber permits the beam to be directed in different directions and allows endoscopic application. The mode and how the laser beam is configured also determine depth of penetration and the amount of latent thermal damage. There are three modes used in delivering laser beams: continuous mode, chopped mode, and superpulse mode. The advantages of the chopped and superpulse modes over the continuous mode are energy efficiency, a decrease in lateral thermal damage, and greater tissue penetration. The continuous mode does not allow marginal tissue cooling during cutting. In the chopped and superpulse modes, cycles of energy are delivered to tissue, which allows cooling between cycles. The faster the laser beam is pulsed, the greater is the amount of energy delivered to the tissue and the deeper the penetration. Choice of which surgical laser to use depends on the method of irradiation delivery, power output, cost, size, and laser–tissue interaction.

### Tissue Interaction

The laser’s wavelength and frequency determine how it will interact with tissue. Tissue reacts to lasers in one of four ways, or in a combination of any of the four: (1) absorption, (2) reflection, (3) transmission, and (4) scatter (Fig. 16-5).

Absorption represents conversion of laser irradiation into heat, resulting in an incision or tissue vaporization. Denaturation of protein occurs when tissue is heated...
between 60° and 70°C and causes coagulation necrosis. Tissue vaporization occurs at 100°C, resulting in cellular explosion. Scattering and reflection cause additional tissue loss. Scattering depends on both the frequency of the energy delivered and the tissue absorption characteristics. Cellular constituents do not equally absorb laser irradiation. Transmission through tissue or fluids surrounding tissue occurs when the absorption curve of pigments, proteins, or fluids does not match the wavelength of the laser beam. The eye is a good example of this laser energy–tissue interaction, because laser irradiation in the visible and near-infrared spectrum are transmitted easily through the clear cornea and lens to be absorbed by the pigmented retina. Water, as an example, absorbs light in the far end of the light spectrum, whereas melanin and hemoglobin absorb light in the near-infrared end of the spectrum. Therefore, the cornea, which contains water, absorbs laser irradiation from the far-infrared spectrum, preventing deeper transmission.

### Laser Safety

Laser safety is important because a collimated laser beam can be emitted over a great distance without attenuation. Lasers have been classified for safety by the Bureau of Radiological Health and the Food and Drug Administration. These agencies classify lasers on the basis of energy output and accessibility to the irradiation emitted. Surgical lasers emit high energy levels and belong to class IV lasers, which are considered the most hazardous because burns can result from direct application or from deflected or reflected beams of irradiation. All personnel within an area where surgical lasers are operated need to be aware of the potential damage that can be caused by the apparatus. The patient, operator, and other personnel should be protected. All users should understand the safety standards required for each laser they intend to use. For example, the beam of the CO2 laser is attenuated by water; therefore, drapes should be covered with sterile, moistened towels to avoid fires in the surgical area. Protection of endotracheal tubes is of the greatest importance, because they carry high concentrations of oxygen; and airway fires are fatal.

Although instruments with a reflective surface can be used with lasers, it is best to use anodized instruments, decreasing the potential of reflected or scattered beams onto adjacent tissues or toward people in the area. Eye damage caused by reflection is a major safety concern. Specifically designed glasses or goggles should be used to filter out the damaging irradiation. The CO2 laser has a high propensity for damaging the cornea and requires the operator to wear simple plastic goggles. The argon, potassium titanyl phosphate (KTP), diode, or various yttrium aluminum garnet (YAG) lasers require specific filtered lenses to prohibit the beam from causing retinal damage. Endoscopic application of lasers should also include protective eyewear or should be performed with the assistance of a video camera attached to the endoscope. This negates the possibility of infrared irradiation being reflected back through a fiberoptic channel and directly into the eye of the operator. Signs for laser dangers should be posted immediately outside the operating room, and the doors of the room should be locked during laser surgery. Glass windows in operating room doors and walls should be covered with protective shades, and equipment to extinguish a fire should be immediately available.

![Figure 16-5. Four possible laser tissue interactions. Dominance is determined by laser beam wavelength.](image-url)
Video viewing is also preferred because magnification of the target tissue improves the precision of directing the laser beam (Fig. 16-6). Endoscopes constructed with a built-in video chip camera should be certified as laser protected by the manufacturer. Video endoscopes that are not certified will produce a "whiteout" when the laser is activated, preventing observation of laser tissue interaction. Most endoscope manufacturers provide protection for neodymium (Nd):YAG laser irradiation. Diode lasers at a slightly different wavelength can cause a whiteout when the laser is activated. It is important to specify which laser wavelengths will be used when questioning the endoscope manufacturer or representative.

The laser fiber used for transendoscopic application should protrude at least 1 cm out of the distal biopsy port to prevent heat or hot debris from damaging the endoscope. Endoscopes that have a darkened surface at the distal end are more susceptible to damage than a metal or a lighter-colored material, because dark materials absorb infrared irradiation. After finishing a laser procedure, the laser fiber should be examined to ensure that there is no debris attached that could lacerate the inner channel of the endoscope when the fiber is retracted. The fiber should be allowed to cool before pulling it into the biopsy channel.

SUPPORT EQUIPMENT

Support equipment is considered essential for transendoscopic laser application. Commercially available bronchosophagclosed grasping forceps, endoscopic snares, and polyethylene tubing are used to irrigate tissue or apply local anesthetics or medications through the biopsy channel.11,12 Transendoscopic surgery for horses requires a flexible endoscope of at least 60 cm in length, preferably equipped with a video system.11

Some newer endoscopes contain a second channel, which may have several advantages for laser surgery, as it provides a route for the removal of smoke, the introduction of additional instruments, and direct irrigation. Endoscopic irrigation is advantageous for two reasons: it provides cool water to the tissues surrounding the target and, when applied in a pulsating mode, it can be used to flush carbonized debris from the tissue. It is crucial that the endoscope have at least a 2.7-mm biopsy channel to allow the passage of the laser fiber. Evacuation of smoke is important, because smoke irritates mucous membranes and obscures vision.7,13 When a second biopsy channel is not available, smoke is removed by suction or by mechanical filtration attached to a flexible tube passed through the patient’s opposite nostril. If standard suction is chosen, an in-line filter is necessary to prevent smoke particles and debris from soiling and obstructing the equipment.8 The smoke produced during cell vaporization is referred to as laser plume. When a laser is used in general surgery, an air filtration device should also be employed to remove smoke from the surgical area.

RESTRAINT

Horses should be placed in stocks and heavily sedated for standing transendoscopic laser surgery. Xylazine (0.3 to 0.5 mg/kg) and butorphanol tartrate (0.025 mg/kg), in combination, provide sedation and analgesia.8,11,14 Two alternative drug combinations that can be used for restraint are acepromazine maleate (0.033 mg/kg IV), followed by detomidine hydrochloride (0.011 mg/kg IV), or a combination of xylazine (0.4 to 0.6 mg/kg IV) and acepromazine maleate (0.02 to 0.04 mg/kg IV).15 Topical anesthesia of mucosal surfaces can be provided by either local irrigation or infiltration. For upper respiratory work, the horse’s head
should be cross-tied in a position that prevents tracheal compression and at a level suitable for endoscope placement.

SURGICAL LASERS

CO₂ Laser

Of all the surgical lasers, the CO₂ laser has received more recognition and is used the most in general surgery. The CO₂ laser, which produces a beam of irradiation in the far-infrared range (10,600 nm), and was the first to be applied surgically, is considered excellent for incising tissue. Because its beam is absorbed rapidly, it produces little latent thermal damage. Its success as a hemostatic device is generally considered poor because it coagulates vessels only up to a diameter of 0.5 mm. Its physical appearance is easily recognized; its beam is routinely transmitted through an articulating arm to the target tissue (Fig. 16-7). A series of mirrors and focusing lenses are incorporated into the articulating arm. The mirrors carry the laser beam and the lenses form a small focal spot. This articulating arm restricts the laser’s use to lesions within the line of sight. By connecting it to operating microscopes, bronchoscopes, or laparoscopes, applications within certain hollow organs or passageways are possible. Even when coupled to these devices, its application is still restricted to lesions within a straight line or lesions that can be visualized by reflection in mirrors.

Newer CO₂ lasers producing up to 20 W can use a hollow light guide to transmit the irradiation (see Fig. 16-7). Hollow light guides are small flexible metal tubes (4 to 5 mm in diameter) with highly polished or reflective coated inner linings. The hollow light guide is less cumbersome to use in surgery than the articulating arm. At the distal end is a hand piece in which a small tip or nozzle is inserted to focus the irradiation. The smaller the tip, the smaller is the focal point, and thus a greater concentration of irradiation is emitted. In general surgery, the wave-guide hand piece can easily be covered with a sterile barrier.

For endoscopic application, small (1.5 to 2 mm) metal hollow light guides were manufactured that were up to 1 m in length. The metal construction significantly retarded flexibility of the endoscope and easily damaged its biopsy channel. In 2004, a very flexible laminated plastic waveguide, the OmniGuide, was constructed for CO₂ laser transmission. The wave-guide is over 1 m in length, and its distal tip is under 2.7 mm in diameter, allowing it to be passed through the biopsy channel of most endoscopes.

The infrared beam of the CO₂ laser is primarily absorbed by water, raising its temperature to a superheated steam within the cells and causing their membranes to explode. Adjacent tissue and water may serve as heat sinks, producing latent thermal damage. Studies have demonstrated that there is a delay in healing, similar to that produced by electrosurgery, when the CO₂ laser is used for skin incisions. For this reason, many surgeons prefer to perform the initial skin incision with a scalpel rather than with the CO₂ laser. Debulking of neoplastic masses with the CO₂ laser is beneficial because it seals small vessels and lymphatics, which could disseminate tumor cells. Sealing of lymphatics and small vessels is also advantageous because it decreases postoperative edema, and pain is mitigated through transection and sealing of small nerves. The surgeon can employ a “no touch” technique with this laser (i.e., tip of the laser never touches the tissue) and tissue separation and penetration depth is visualized as it occurs. In veterinary surgery, the CO₂ laser is generally used for removal of skin masses, general cutting, sterilization of an infected area, or sealing of small vessels and lymphatics. It may also be used in the defocus pattern to produce photovaporization for removal of small tumors, for sterilization of infected wounds, or for shaving away several layers of surface cells.

Figure 16-7. CO₂ laser delivery systems. A. Articulating arm containing a series of mirrors and focusing lenses used to deliver irradiation to the target tissue. B. A hollow flexible light guide is used in conjunction with a focusing hand piece as a substitute for an articulating arm.
The destructive potential of the CO₂ laser is directly proportional to its power output. Because its absorption coefficient in water is very high, the surgeon should use the laser at its highest power in a motion that is as swift as possible. Irradiation is significantly attenuated as it passes through hollow light guides. The smaller and longer the wave-guide, the greater the loss of power at the emitting end. Therefore, the light guides constructed for endoscopic use need to be coupled to a CO₂ laser that produces 20 W or greater to perform transendoscopic surgical procedures. Transendoscopic application of CO₂ laser irradiation through the hollow OmniGuide broadens the versatility of the CO₂ laser. Laser tissue interactions at this wavelength produce less latent thermal necrosis than any other laser, which should improve the surgeon’s accuracy and decrease healing time. In the future, these two factors will play an important role in the selection of a laser for endoscopic application in the veterinary field.

**Nd:YAG Laser**

In large animals, the Nd:YAG laser was the most popular laser applied endoscopically from 1984 to the mid 1990s.* The medium of this laser produces a wavelength of 1064 nm, which allows transmission through quartz fibers. The photons produced by this laser are not absorbed by water. This laser’s beam is in the near-infrared portion of the light spectrum; it exhibits stronger tissue absorption than the CO₂ laser. The Nd:YAG laser is better suited than the CO₂ laser for volumetric heating of large tissue masses. The two primary agents that give living tissue its color, melanin and hemoglobin, absorb this laser’s wavelength equally. It is the characteristic of scatter and absorptive heating that gives the Nd:YAG laser the unwanted quality of producing substantial latent thermal tissue necrosis compared with the CO₂ laser. This laser does, however, have the advantage of coagulating substantially larger vessels than the CO₂ laser. It is reported to produce good hemostasis in vessels up to 4 mm in diameter.6 This characteristic is enhanced by its lack of absorption by water, which allows its beam to pass through many body fluids. With proper training, the surgeon can anticipate the amount of latent thermal necrosis that will occur. The Nd:YAG laser has been widely used in the upper respiratory area because of its ability to transmit its energy through fiberoptic cables, provide coagulation, and efficiently photo-vaporize tissue transendoscopically.

**Diode Laser**

Diode lasers are advantageous because of their semiconductor construction. They are generally small and portable and require less current than lasers using a medium. The efficiency of the diode laser exceeds that of most other lasers: 20% to 80% of input power is converted to laser energy. Diode lasers manufactured for veterinary surgery produce wavelengths of 810, 980, and 10,600 nm. The lower-wavelength lasers use inexpensive flexible quartz fibers to transmit their irradiation in the free-fiber or contact configuration. For contact application, fibers with a sculptured tip in the form of a cone, wedge, or ball are available.8,17 The area where diode lasers differ from larger resonating chamber lasers is in power output. Most diode lasers are rated with power outputs up to 25 W; a few diode lasers have a power rating in the 50- to 60-W range. The decreased power output may increase the time that it takes to perform a procedure, because tissue penetration is decreased. Cooling of the internal diode array is critical to their stability and longevity. Therefore, to maintain a small size, manufacturers limit the power output to prevent overheating. However, the diode lasers have gained popularity because they can be manufactured at selective wavelengths and, in many cases, have replaced larger, more cumbersome lasers such as the Nd:YAG and argon lasers. User-friendly characteristics include a high electrical-to-optical efficiency, light weight, compact size, air cooling, and operation from a standard 110 variable AC electrical outlet. In large animal surgery, they can be used transendoscopically to treat many of the upper respiratory diseases.

**Argon, KTP, and Holmium Lasers**

In veterinary medicine, the argon laser (488 and 515 nm) has been used as the pump source for the dye laser. In the dye laser, a liquid phase moves through the medium and is excited by the argon laser. Therefore, wavelength selection is possible by changing the dye exposure. Because diode lasers can be manufactured at any wavelength, they have been also produced to mimic the dye pump laser. Tunable selection of wavelength is important for the excitation of hematoporphyrin derivatives, referred to as photodynamic therapy. Photodynamic therapy is based on the principle that abnormal tissues, primarily cancer cells, selectively retain compounds on the basis of hematoporphyrin derivatives. Once the body’s normal tissues have excreted the hematoporphyrin, tumorous tissue may be exposed to a set wavelength of light, causing an internal reaction and the release of superoxide radicals. This selectively kills tumor cells without destroying normal tissue.

A flash lamp–pulsed dye laser (504 nm) has been used to fragment uroliths in horses.19,20 The laser fiber is applied transendoscopically, with the endoscope passed up the urethra or through a subischial urethropotomy incision. The procedure can be performed on the standing horse, but best results are achieved with general anesthesia and the horse placed in lateral recumbency. The laser fiber must make contact with the solid calculus for the pulses to properly fragment it. Complete fragmentation of a calculus of 4 to 6 cm in diameter requires thousands of laser pulses over several hours, and debris is removed by periodically replacing the endoscope with a lavage system.20 For more information on this technique, see Chapter 71.

The KTP laser (532 nm) has been used in general surgery and is excellent for incising tissues. Its irradiation beam is transmitted through fiberoptic cables, which influences its popularity.

The holmium laser (2100 nm) uses fiberoptic transmission for its irradiation beam. It is very effective in liquid media such as joint fluid. Therefore, this device has become popular in upper respiratory, arthroscopic, urogenital, and ocular surgery. In arthroscopy, this device is applied to shrink periarticular tissues, transect ligaments, ablate syn-
ovary membrane and villi proliferations, and shave off cartilage and meniscal lesions. Arthroscopic removal of plantar or palmar chips of the proximal phalanx is greatly assisted by the use of the holmium laser to ablate the proliferative synovial membrane in the region, thus facilitating better visual perception of the surgical field and ensuring that the entire chip has been removed.22 Application of the holmium laser in upper respiratory surgery is limited because of the need for contact application of the laser fiber tip for tissue removal. Smaller diode lasers have primarily replaced it in this field of surgery. The holmium laser has been applied to perform lithotripsy, but it has not been as beneficial or as popular as other lasers for this procedure.

DELIVERY SYSTEMS

For the Nd:YAG, holmium, KTP, argon, diode, and several other lasers, energy can be transmitted through small quartz fibers. These fibers are constructed in two forms, solid and coaxial, and they are between 3 and 4 m long (Fig. 16-8, E and F). Most outside diameters are less than 2.7 mm, allowing the fibers to pass through the biopsy channel of an endoscope.8,11,12 Initially, devices such as sapphire crystals were connected to the ends of the solid quartz fibers, which, upon absorbing energy, produced a high temperature at the tip and were used for cutting and ablation tissue.

This form of delivery is referred to as contact delivery, in that the device or the end of the quartz fiber has to remain in contact with tissue to transmit the laser’s thermal energy.8,9,12 Currently, contact delivery systems do not require the sapphire end piece for the fiber to be used either endoscopically or hand held in general surgery. Fibers are now manufactured so that the ends can be either polished or cleaved for multiple uses for contact cutting. These fibers are particularly amenable for use with diode lasers that produce 15 to 25 W. A large-animal veterinarian using this system with one of the diode lasers can easily perform surgical procedures that simply require an incision to relieve the animal of an upper respiratory disorder.

Fiber longevity is increased by cycling the laser’s irradiation when activated. For example, using a diode laser set at 18 W with a 600-nm fiber and cycle settings for 0.8 seconds on and 0.2 second off allows cooling of the fiber’s cutting end. This could double the fiber’s usable application time before it has to be replaced or cleaved. With the older Nd:YAG laser and high-power output diode lasers producing between 50 and 60 W, a second option, referred to as noncontact delivery, is available for delivery of laser irradiation. In this form of delivery system, the quartz fiber is further enclosed by a polyethylene casing, which carries cooling inert gas such as nitrogen or carbon dioxide, and internally, the laser contains aiming beams whose wavelength is within the visible range8,11,23 (see Fig. 16-8, F). With the contact form of cutting, the incision that is produced is similar to that made with a scalpel.12 The disadvantage is that the incision must be made before the surgeon can visualize the depth of the tissue that has been disrupted. With noncontact cutting, the fiber is several millimeters away from the tissue, and the surgeon has the advantage of visualizing the depth of the cut as it occurs. Noncontact cutting is also performed using hollow light guides. Those produced for transendoscopic application are smaller than those used in general surgery, which are hand held (see Fig. 16-8, C and D).

APPLICATION OF LASERS

CO2 Laser

Skin tumors, such as sarcoiids or squamous cell carcinoma, are easily ablated with the CO2 laser.7,8,24 When the animal is not placed under general anesthesia, it is sedated and local anesthetic is infused sublesionally. In certain cases, the CO2 laser is used as a scalpel for tissue resection. However, skin tumors that are sufficiently raised above the base of the skin are best removed through sharp scalpel dissection at or below the skin surface. The laser is then applied in the defocused pattern, and all remaining tumorous tissue is removed. Wounds are generally left to heal by second intention. If wounds are closed, skin sutures should be left in place long enough to ensure that complete wound healing occurs prior to their removal. Laser ablation of sarcoiids, particularly in the auricular region, is favored over freezing.

Periocular squamous cell carcinomas are excellent indications for CO2 laser application. Advantages over freeze-
ing techniques include better control and significantly less swelling and pain after tumor removal, because the lymphatics, veins, and nerves are sealed. Twists of the eyelids or nictitating membrane can be removed without general anesthesia, although it is required for ablation of squamous cell carcinomas of the cornea. The laser is usually applied at a setting between 10 and 20 W for ablation of tissue around the cornea, and between 3 and 8 W for vaporizing a tumor off the cornea. Practice and precision are required when working around the eye, especially when the cornea is involved.

The CO$_2$ laser may be used to prepare granulation beds for skin grafting. An output of between 15 and 25 W is selected, and the laser is applied in a defocused pattern to remove exuberant granulation tissue to a level below the skin surface. Periodically, the area should be flushed with normal saline or daubed with moistened, sterile gauze sponges to remove carbonized tissue debris. The CO$_2$ laser is superior to the steel scalpel for the preparation of a graft bed, because it seals the small vessels, thus reducing hemorrhage and providing better visualization of the tissue surface. The CO$_2$ laser sterilizes the tissue surface, and repeated applications produce a healthy-appearing granulation bed. The accuracy of tissue removal is greatly improved by directing the laser’s irradiation through a mechanical scanner, which controls the speed and sweep of the beam over the lesion area.

The CO$_2$ laser can be used to create recipient pockets for pinch grafts. The power setting for this purpose is 7 to 15 W in the focus mode. The pockets are created at a 45- to 60-degree angle to the tissue surface in a downward direction. The dimensions of the pockets should be between 2 and 4 mm in diameter and from 3 to 4 mm in depth. The advantage of using the CO$_2$ laser is the no-touch technique of tissue sterilization, combined with decreased hemorrhage. Minimal additional damage occurs if the laser is used in a chopped or superpulse mode. Flushing of the pockets is necessary to remove the carbonized tissue debris. Best results are obtained by bandaging the wound for 12 to 24 hours before skin grafting. After that, bandages are removed, the area is flushed, and a skin graft (pinch grafts) is placed into each of the previously created pockets. The rationale for the delay between pocket creation and graft placement is improved capillary growth and graft survival. For additional information on skin grafting, see Chapter 25.

In the urogenital system, the CO$_2$ laser has advantages over freezing or steel scalpel surgery. For example, in a patient with penile carcinoma, removal can be performed under local anesthesia. Pedunculated masses are resected using the CO$_2$ laser in a focused pattern, and the edges are further treated in the defocused pattern. Healing occurs by second intention.

Laser palmar digital neurectomy was first performed using the CO$_2$ laser. Horses are placed under general anesthesia, and after the paresthesia is prepared for aseptic surgery, the nerve is isolated through a small incision. Laser irradiation is used to transect and remove a segment of the nerve. The thermal effect of the laser’s irradiation causes coagulation at the point of transection, which reduces the possibility of axonal reconnection or neuroma formation. Several other lasers, including the Nd:YAG and diode lasers, have been applied in a similar fashion with good results.

Transendoscopic Application: Nd:YAG, Diode Lasers, and CO$_2$ Wave-Guide

Entrapment of the Epiglottis

Correction of the entrapment by the aryepiglottic fold is achieved by transendoscopic axial division using contact or noncontact delivery fibers in conjunction with the Nd:YAG and diode laser, or OmniGuide, coupled to the CO$_2$ laser. The Nd:YAG is applied at 100 W using a noncontact fiber or at 15 to 20 W using a contact fiber. In performing a release of the aryepiglottic fold, care should be taken to avoid secondary thermal damage to the epiglottis, particularly at its tip. It is helpful to make an initial 1- to 1.5-cm horizontal incision just underneath the tip of the epiglottis to assist in providing a complete release of the aryepiglottic fold and decrease the possibility of reentrapment. The laser energy is then applied in a straight line beginning at the caudal border of the aryepiglottic fold and ending at the tip of the epiglottis. Initially, the incision is shallow and provides a path for the laser to track. This path is then deepened with each passage of the laser fiber until release is achieved. As the incision is deepened, inherent tension causes the edges to retract laterally, exposing fresh tissue for the next laser pass. In some instances, premature release of the entrapment may occur before the mucosa is entirely divided, or, if a thickened entrapment is present, it may fail to completely retract beneath the epiglottis. The bronchoesophageal grasping forceps should be employed to elevate the tissue to facilitate completion of the incision. On occasion, when the surgeon is unable to elevate the tissue, laser blanching may be performed to produce delayed necrosis, which results in further tissue separation. Post-treatment evaluation should be performed 14 days after the release of epiglottic entrapment and again at 30 days.

Dorsal Displacement of the Soft Palate

Under general anesthesia, the CO$_2$ laser can assist in performing a myectomy, in which a portion of the muscle bellies of the sternothyroideus, sternohyoides, and omohyoides muscles are incised and resected (see Chapter 43). Transendoscopic application of a diode laser has been used in contact mode to blanch focal points along the caudal border of the soft palate in combination with the myectomy procedure. The premise behind this form of treatment is that the thermal energy will produce scar tissue formation, thus stiffening the soft palate and preventing it from dorsally displacing above the epiglottis. No more than 1000 J should be applied to the soft palate. Applying too much energy to the soft palate can result in complete necrosis of the laser treated area.

Respiratory Masses (Pharynx, Larynx, and Trachea)

Tracheal, pharyngeal, and laryngeal masses including lymphoid hyperplasia, granulomas, and cancer can easily be removed using any of the lasers in either the contact or noncontact delivery configurations. Large masses can be separated off the pharynx and retrieved using a grasping forceps or an endoscopic snare. Similarly, granulating
masses on the surface of the arytenoid cartilage can be cauterized in a similar fashion. Infected fistulas within the arytenoid cartilage can be cauterized with laser irradiation. The laser fiber is inserted into the fistula, either transendoscopically or through a laryngotomy incision performed on the standing sedated horse. Transendoscopic drainage or vaporization of respiratory abscesses can be performed using the Nd:YAG or diode laser.

**Vocal Cordectomy and Ventriculectomy**

Ventriculectomy or vocal cordectomy can be performed transendoscopically. For laser ventriculectomy, a high-powered laser Nd:YAG or diode laser (50 to 100 W) is required to achieve vaporization of the ventricle’s mucosal lining. The lining of the ventricle is blanched using a coaxial laser fiber in a noncontact configuration, totaling up to 3500 J of energy.34

Swelling of the mucosa develops very rapidly, so the initial irradiation should be directed deep into the sack with the fiber and then drawn toward the opening as the mucosal surface swells and is coagulated. An alternative method is a vocal cordectomy, in which the vocal fold is incised by using a contact fiber and bronchoesophageal forceps. The bronchoesophageal forceps are passed through the opposite nostril to grasp the fold and provide traction as the laser fiber is gently drawn along the edges of the vocal fold to separate it from the laryngeal wall. For more details on these surgeries, see Chapter 44.

**Progressive Ethmoid Hematoma**

Because definitive treatment of a progressive ethmoid hematoma remains controversial, lasers have been employed over the last 20 years to treat primary lesions and ablate early recurrence. It appears that the most effective laser treatment is reserved for those lesions that appear to originate under the middle nasal conchae, or for recurrences that appear after sinus surgery is performed.38

For masses appearing to arise from the ethmoid turbinate area and not originating in the paranasal sinuses, initial direct injection of 10% formalin may be considered prior to transendoscopic laser ablation. Two weeks after injection of formalin, a small residual portion of the ethmoid hematoma may remain in the lower ethmoid turbinate areas. The remaining lesion can be approached transendoscopically and irradiated using either noncontact 100-W Nd:YAG laser, 50-W or greater diode laser, or CO2 laser coupled with the OmniGuide.

An alternative to formalin injection is direct laser irradiation. This requires a high-wattage laser in which the laser energy is directed to the center of the mass protruding into the nasal pharynx. Substantial energy (30,000 to 40,000 J) is used to thermally debulk the mass. In this procedure, laser energy is directed into the center of the lesion, thermal necrosis produces shrinkage within several days, and an endoscopic snare can be used to remove necrotic tissue. Fewer laser applications are required to treat a small mass or early recurrence. Capsular excision followed by evacuation of the contents and dissection of the origin of the ethmoid hematoma has been described using contact laser scalpel technique. The procedure is performed through a sinusotomy approach, with the horse placed under general anesthesia. Application of the laser provides better visibility within the sinus compartment by decreasing hemorrhage. Recurrence of this lesion is common, and repeated laser ablation via endoscopy is a viable method of controlling tumor regrowth.

**Guttural Pouch Tympany**

Before standing laser surgery is performed, foals should be evaluated for aspiration pneumonia, and if it is present, appropriate systemic antibiotics should be administrated. A Chamber’s catheter is inserted into the larger of the two distended guttural pouches. At this time, deflation of both guttural pouches signifies to the surgeon that the guttural pouch that initiated the distention has been identified if the tympany is not bilateral. Bilateral cases do occur, although they are rarer than unilateral cases. The Chamber’s catheter in the guttural pouch is rotated so that an endoscope passed up the opposite nostril can identify tented mucosa just inside the guttural pouch. The laser of choice is the Nd:YAG, or a high-powered diode laser using noncontact delivery fiber, or the OmniGuide CO2 fiber directed at the tented mucosa. Laser irradiation is stopped when a 5-to 10-mm hole has been created between the pharynx and the guttural pouch, and when the ball on the end of the Chamber’s catheter can be identified. A no. 24 French catheter is then inserted through the hole and allowed to remain in place for at least 14 days so that a permanent fistula is formed between the guttural pouch and the pharynx.

Removal of a portion of the median septum separating the two guttural pouches can be performed using contact or noncontact transendoscopic laser technique. Creation of a fenestration is technically more difficult than creating a fistula between the guttural pouch and the pharynx and has a greater potential risk of causing thermal damage to the vessels and nerve located within.

**Cysts: Subepiglottal, Dorsal Pharyngeal, and Intratrauterine**

Subepiglottal, dorsal pharyngeal, and nasal cysts can be diagnosed by either radiographic means or endoscopic visualization. Standing laser ablation requires a high-powered Nd:YAG, diode, or CO2 OmniGuide laser. Initially, the surface of the cyst is blanched while applying the laser energy in a sweeping motion across the visible surface. The purpose is to cause latent thermal necrosis, so that after the cyst is evacuated additional tissue will slough, preventing premature closure of the incision, and recurrence. The laser is then aimed at the most dependent portion of the cyst, and it is irradiated until fluid drains through the incision. Once the cyst is completely drained of fluid, all portions of the cyst still visible are irradiated. Sometimes, subepiglottal cysts prematurely disappear from view below the soft palate. An endoscopic snare or bronchoesophageal grasping forceps can be used to reposition the cyst for completion of the procedure. A post-treatment examination should be made approximately 14 days after surgery and again at 1 month.

Ablation of an intrauterine cyst requires an endoscopic fiber that provides a high-volume flow of inert gases such as...
CO₂ or nitrogen to maintain insufflation of the uterus. Laser application mimics the technique used with respiratory cysts, except that care should be taken to not irradiate the base of the cyst, as this could result in either immediate or latent penetration of the uterine wall.³²,³⁴,³⁵ Assessment after the ablation is performed by transrectal ultrasonography, and a small uterine scar can be expected to remain at the surgical site after 30 days.

COMPLICATIONS

Although it is frequently successful, standing transendoscopic laser correction of respiratory disorders has the potential for incomplete correction and recurrence. The anatomic location of the lesion and the movement of surrounding structures contribute significantly. For example, complete photoablation of an ethmoid hematoma with its origin located deep within the ethmoid turbinate is difficult to achieve. Similarly, dorsal displacement of the soft palate may visually obscure an epiglottic entrapment or subepiglottal cyst during the treatment procedure, resulting in incomplete correction. Clients should be made aware that such circumstances may require repeated attempts at correction over several days, or eventually surgery under general anesthesia. Before the initiation of any procedure, proper laser function and beam alignment should be confirmed.

Large-vessel laceration is a potential complication, particularly when the laser is applied within the guttural pouch. Additionally, the nerves traversing the guttural pouch may be damaged by direct laser application or by general heating of the surrounding tissues. Allowing periodic cooling or evacuation of heated air can minimize this. This is of concern when applying any laser within hollow organs or enclosed spaces such as the uterus, trachea, urethra, and bladder. Hemorrhage that cannot be immediately stopped by laser irradiation will obscure the target tissue. Blood also absorbs various laser wavelengths, which will decrease the cutting efficiency of the laser’s irradiation. Continuation of the laser procedure then becomes dependent on when hemostasis occurs.

The Nd:YAG laser and those lasers close to its wavelength tend to produce latent necrosis secondary to scatter irradiation.¹⁴ Conservative application is indicated when there is a potential to destroy more tissue than is desired or to inadvertently puncture a hollow organ.

Damage to endoscopic equipment from irradiation backscatter or direct irradiation when the distal scope end is folded back 180 degrees should be avoided. Intrareoscopic damage can occur if hot tips or fibers are pulled through the instrument. Laser fibers coated with debris can lacerate fragile biopsy channels. If an abnormality is observed in the laser fiber, the laser should be inactivated, the endoscope removed from the patient, and the fiber inspected prior to pulling it through the biopsy channel.

SUTURE MATERIALS AND PATTERNS

CHAPTER 17

Suture Materials and Patterns
LeeAnn W. Blackford
James T. Blackford

SUTURE MATERIALS

Sutures serve an important function in wound repair. They are necessary to ligate blood vessels and to hold tissues in apposition as they heal. Suture materials should be selected with regard to their physical and chemical characteristics and the biologic response they elicit from the host. The ideal suture material should have the following properties:

- It should be suitable for any operation.
- It should be easy to handle.
- It should elicit minimal tissue reaction without inducing an environment favorable to bacterial growth.
- It should have high tensile strength and a small diameter.
- It should provide good knot security.
- It should be nonelectrolytic, nonwicking, nonallergenic, and noncarcinogenic.
- It should be easy to sterilize and economical to use.
- Once it has served its purpose, it should be absorbed with minimal tissue reaction.

The ideal suture material does not presently exist, but many of the available materials possess a majority of the ideal properties. Knowledge of the advantages and disadvantages of each suture material allows the surgeon to make an informed choice. The type of tissue involved, the reason for suture application, the patient, and the location and condition of the wound should be considered when choosing a suture material. Although knowledge of the properties of the suture materials is important, more vital is the surgeon’s technique in closing the wound. A good surgeon can usually achieve satisfactory results with any type of suture material.2

Biologic Properties

Sutures are classified as absorbable or nonabsorbable. Absorbable sutures undergo degradation and rapid loss of tensile strength within 60 days.1,3 Absorption occurs either by enzymatic degradation and subsequent phagocytosis (e.g., surgical gut) or by hydrolysis, a process in which the suture is broken down by the addition of water and then metabolized. Nonabsorbable sutures retain tensile strength for more than 60 days.4 Absorption must be distinguished from loss of tensile strength, which has greater significance. Tensile strength is a measure of how much pull a suture can withstand before it breaks. Suture strength is essential for the early healing of wounds, and tensile strength retention is critical in delayed wound healing or when permanent retention of a prosthesis (e.g., a laryngeal prosthesis) is required.3 Characteristics of the most commonly used absorbable and nonabsorbable suture materials are found in Tables 17-1 and 17-2. Additional information on the physical characteristics and composition of suture materials is found in Chapter 9.

SUTURE MATERIALS

Sutures serve an important function in wound repair. They are necessary to ligate blood vessels and to hold tissues in apposition as they heal. Suture materials should be selected with regard to their physical and chemical characteristics and the biologic response they elicit from the host. The ideal suture material should have the following properties:

- It should be suitable for any operation.
- It should be easy to handle.
- It should elicit minimal tissue reaction without inducing an environment favorable to bacterial growth.
- It should have high tensile strength and a small diameter.
- It should provide good knot security.
- It should be nonelectrolytic, nonwicking, nonallergenic, and noncarcinogenic.
- It should be easy to sterilize and economical to use.
- Once it has served its purpose, it should be absorbed with minimal tissue reaction.

The ideal suture material does not presently exist, but many of the available materials possess a majority of the ideal properties. Knowledge of the advantages and disadvantages of each suture material allows the surgeon to make an informed choice. The type of tissue involved, the reason for suture application, the patient, and the location and condition of the wound should be considered when choosing a suture material. Although knowledge of the properties of the suture materials is important, more vital is the surgeon’s technique in closing the wound. A good surgeon can usually achieve satisfactory results with any type of suture material.

Biologic Properties

Sutures are classified as absorbable or nonabsorbable. Absorbable sutures undergo degradation and rapid loss of tensile strength within 60 days. Absorption occurs either by enzymatic degradation and subsequent phagocytosis (e.g., surgical gut) or by hydrolysis, a process in which the suture is broken down by the addition of water and then metabolized. Nonabsorbable sutures retain tensile strength for more than 60 days. Absorption must be distinguished from loss of tensile strength, which has greater significance. Tensile strength is a measure of how much pull a suture can withstand before it breaks. Suture strength is essential for the early healing of wounds, and tensile strength retention is critical in delayed wound healing or when permanent retention of a prosthesis (e.g., a laryngeal prosthesis) is required. Trends in the management of horses with laryngeal hemiparesis/hemiplegia, Clin Techn Equine Pract 2002;1:13.

<td>Has a high initial tensile strength with little or no loss after implantation</td>
<td>One of the strongest nonmetallic suture materials available. Offers prolonged support for slow-healing tissues. Nonwicking. Good handling characteristics</td>
<td>Noncoated polyester has a high coefficient of friction. Coating reduces knot security. Causes the most tissue reaction of the synthetic suture materials. Should not be used in contaminated wounds. Can form sinus tracts</td>
</tr>
</tbody>
</table>
Physical Properties

Sutures are made from naturally occurring substances (e.g., surgical gut, silk), synthetic polymers, or metallic fibers. Sutures are formed as a single strand (monofilament) or multiple strands (multifilament) that are either braided or twisted together. Most surgical staples used in equine surgery are manufactured from stainless steel.

Selecting the Appropriate Suture Material

The selection of suture material should be based on the known biologic and physical properties of the suture, the wound environment, and the response of tissue to the suture. More than 10 suture varieties are available, and some are superior to others in different wound environments.

The suture selected should be as strong as the normal tissue through which it is placed. Skin and fascia are the strongest tissues, stomach and small intestine are much weaker, and the urinary bladder is even weaker. For the first 3 to 4 days, the strength of the sutured wound depends on the suture material. The relative rates at which a wound gains strength and the suture loses strength is important. For example, visceral wounds heal rapidly, gaining strength in 14 to 21 days; therefore, absorbable sutures are adequate for these tissues. However, because fascia heals slowly, attaining only 50% of maximal strength at day 50, nonabsorbable sutures are more suitable for its closure.

When the wounds being sutured are contaminated or infected, the biologic effect on the healing process is especially important. Most sutures are known to potentiate the development of wound infection. Monofilament sutures are not as likely as multifilament sutures to exhibit capillarity (a wicking action that allows infection to travel along the suture strand), and therefore they withstand contamination better. Sutures with the lowest reported incidence of infection when used in contaminated tissues include polyglycolic acid, polyglactin 910, monofilament nylon, and polypropylene. The amount of suture material used in contaminated wounds should be minimized, because even the least reactive suture impairs the ability of the wound to resist infection.

Selecting the Appropriate Suture for a Specific Tissue

The sutures recommended for specific tissues are the following:

- Skin. Monofilament nylon, polypropylene, and polybutester are preferred for skin sutures. Sutures that exhibit capillarity or are reactive should be avoided.
- Subcutis. Synthetic absorbable sutures are preferred.
- Fascia. Synthetic nonabsorbable sutures are recommended if prolonged strength is required, although synthetic absorbable sutures have been effective.
- Muscle. Synthetic absorbable or nonabsorbable sutures may be used effectively in muscle. Nylon and polypropylene are recommended for use in cardiac muscle because of their superior mechanical properties.
- Hollow viscus. Surgical gut, polyglycolic acid, polyglactin 910, polyglercaprone 25, glycomer 631, and monofilament nonabsorbable sutures may be used in viscera. Polyglycolic acid has been observed to absorb prematurely in urine. Multifilament, nonabsorbable sutures should be avoided because they serve as a nidus of calculus formation.
- Tendon. Nylon and stainless steel are commonly recommended for tendon repair. Polidioxanone and polybutester have been suggested for equine flexor tendon repair because they may decrease adhesion formation associated with the prolonged presence of suture. The newly available polyglyconate suture may also be effective as a tendon suture.
- Blood vessel. Polypropylene is the least thrombogenic suture and is the material of choice in vascular repair. Nylon and coated polyester have also been used.
- Nerve. Nylon and polypropylene are recommended for peripheral nerve repair because tissue reactivity is the most important consideration.

**SURGICAL METHODS**
Selecting the Appropriate Suture Size

When selecting the proper diameter of suture, the following principles should be considered:

- The strength of a wound is more dependent on the involved tissue’s ability to hold a suture than the strength of the suture material itself.¹
- Use of an oversized suture material may weaken the repaired wound by causing excessive tissue reaction.
- A suture’s function is to hold the wound edges together under minimal tension.
- For a wound under tension, increasing suture numbers is better than increasing material size. In general, skin and fascia have the greatest suture-holding power, and fat has the least.

Guidelines for the size of ligature and suture to use for various tissues have not been officially specified for large animal surgery. Table 17-3 reflects the author’s preference in suture sizes for various tissues.

**SURGICAL NEEDLES**

The appropriate suture needle to be used is based on the type of tissue to be sutured, the location and accessibility of the tissue, and the size of the suture material. Suture needles are manufactured from stainless steel and are available as eyed needles, where the suture has to be threaded, or swaged needles with the suture attached to their ends. Swaged needles are less traumatic to tissues, easier to handle, and always sharp because they are used only once and then discarded. Eyed needles are reusable and less expensive than swaged needles, but they cause greater trauma during suture placement because of the bigger diameter of the end and because a double strand of suture is pulled through the tissue, and they become dull with reuse.¹

Surgical needles vary in size, shape, and type of needle point. The important aspects of needle size are the length and diameter (Fig. 17-1). The needle should be long enough to penetrate both sides of the incision. To avoid excessive trauma, the diameter should be the smallest that will penetrate the tissue without bending.¹

The ability of the needle to penetrate tissue depends on the shape of the point and body (Fig. 17-2). Taper-point

**Figure 17-1.** Anatomy of a surgical needle. (Redrawn with permission from Ethicon, Inc, Somerville, NJ, 1999.)

**Figure 17-2.** Various points and shaft designs of suture needles. (Redrawn with permission from Turner AS, McIlwraith CW: Techniques in Large Animal Surgery. Oxford, UK, 1989, Blackwell.)
needles have a sharp point and cylindric body, and they can be used on nonfibrous soft tissues (such as abdominal viscera) with minimal risk to adjacent vessels and nerves. Cutting needles are used to penetrate dense tissues such as fascia and skin. Cutting needles may be conventional (side cutting) or reverse cutting, in which the cutting edge is located on the convex side of the needle. The inner, flat concave surface of the reverse-cutting needle prevents excessive cutting of tissues when the needle passes through them. The design also improves needle strength. The taper-cut needle combines the reverse-cutting point with a round shaft that is useful in delicate fibrous tissue. The special K needle (Deknatel, Inc, Fall River, Mass) is similar to the taper-cut needle and is useful in tough, dense tissues such as the cartilage of the equine larynx. Additional information is found in Chapter 44.

Needles come in various shapes: straight, half-curved, or with a variable curvature (Fig. 17-3). Wound depth, size, and accessibility to suturing are the factors considered when choosing the needle shape. Straight needles are used in accessible sites (e.g., when performing an anastomosis of exteriorized bowel). When suturing within a deep wound, a half-circle or five-eighths-circle needle is more suitable. Long-stemmed needles are used for placing heavy suture materials (e.g., vaginal prolapse). In most other instances, the 3/8 needle is preferred because it requires the least rotational movement of the hand to traverse the tissue.

When choosing a needle, the following factors should be considered:

- The hole made by the needle should be only large enough to permit suture passage, so that the needle does not weaken the tissue.
- The design and diameter of the needle should result in minimal tissue damage and needle breakage.
- The needle should have the appropriate size, shape, and diameter to permit rapid, accurate, and precise suturing.

SUTURE CONFIGURATIONS
Knots and Ligatures
Tying knots rapidly and efficiently is an integral part of any surgical procedure. Types of surgical knots are demonstrated in Figure 17-4. In general, sutures and ligatures (sutures used for occluding blood vessels) are tied in square knots because these are the most secure. The half-hitch is the basic component of three types of knots. Two consecutive half-hitch knots can result in a square knot, a granny knot, or a half-hitch knot. Square knots are made by reversing direction on consecutive half-hitches. Each half-hitch is ideally tightened with even tension on both strands in the same plane as the suture, perpendicular to the incision line. Failure to reverse direction on consecutive throws results in a granny knot. Failure to maintain even tension on the strands or pulling the strands away from the plane of the knot may result in a half-hitch or an asymmetric square knot. Granny and half-hitch knots are prone to slip and generally are not recommended. However, these knots may be used to overcome tissue tension when applying deep sutures or ligatures, because they can be slipped under tension to tighten the suture. When used in this manner, several square knots should be applied on top to prevent slippage.

When the first throw of a square knot does not hold the wound in apposition, a surgeon’s knot may be tied by applying a double twist to the first throw. The surgeon’s knot should be avoided when not needed, however, because it takes longer to tie and places more suture material into the wound. When using chromic gut, a surgeon’s knot is contraindicated. The increased friction weakens the suture by fraying the material at the knot.

During closure of deep layers, tightening the sutures at a 90-degree angle to the suture loop plane or parallel to the...
incision direction facilitates tissue closure, prevents excessive force, and reduces the risk of suture breakage. Attempting to close deep tissue layers by tightening sutures at a 90-degree angle to the incisional plane distracts the superficial layers while deep tissue layers are apposed, which is counterproductive.

Knot-tying techniques and physical characteristics of suture materials influence knot security. In one study, the minimal number of throws needed (including the first) for a secure square knot were determined to be three for catgut, polyglycolic acid, polyglactin 910, and polypropylene and four for nylon and polydioxanone. However, when beginning a continuous suture pattern with square knots, one additional throw was required with surgical gut, polydioxanone, and nylon. Two or three additional throws were required for knot security when using square knots, to end a continuous pattern with all suture materials tested. In this study, the newer suture materials were clearly not included.

Three methods for tying knots are the one-handed, two-handed, and instrument ties. These techniques and other methods of applying ligatures are discussed in depth in the literature. The ability to use all of these techniques gives the surgeon versatility in applying secure ligatures and sutures in every situation.

**Suture Patterns**

A wide variety of suture patterns are available for use in animals. The surgeon should be familiar with the advantages and disadvantages of each and choose one that provides maximal security with minimal alteration of wound healing. The general features and common uses of selected suture patterns are summarized in Tables 17-4 to 17-6. Corresponding illustrations are provided in Figures 17-5 to 17-7.

**Interrupted Versus Continuous Patterns**

Sutures may be placed in an interrupted or a continuous pattern. Interrupted patterns provide more security because failure of one suture does not jeopardize the entire closure. Suture failure in any portion of a continuous pattern may lead to dehiscence of the entire suture line. Interrupted sutures have the disadvantages of leaving a greater volume of suture material in the tissue (in the form of knots), increased surgery time (to tie multiple knots and cut the suture ends), and lower holding power against stress. Continuous suture patterns result in less suture material in the wound and reduced operative time. In terms of wound-bursting strength, a simple continuous pattern is superior to simple interrupted patterns when used in abdominal fascial closure. The continuous suture tends to distribute tension along the entire length of an incision, instead of isolating tension to each individual suture.

**Everting versus Inverting Patterns**

Suture patterns that cause slight eversion are useful for skin closure because skin edges tend to invert during healing. To prevent leakage, inverting patterns are desirable for closure of hollow viscera; however, excessive inversion compromises lumen size.

</tbody>
</table>

Skin closure using a continuous intradermal pattern is popular, especially in conjunction with periosteal stripping. In addition to the technique depicted in Figure 17-5, F, application of the pattern in Figure 17-5, C in a continuous fashion results in secure closure of the skin. The latter technique has better cosmetic properties. Care is taken not to include the epidermis because of the potential development of suture fistulas. Ideally, a 2-0 or 3-0 absorbable monofilament suture material (polydioxanone [PDS] or polyglyconate [Maxon]) with a reverse-cutting or taper-cut needle is used.

Wounds with large defects or tissue loss are difficult to close without tension on the sutures. Tension may cut through or strangulate the tissue, resulting in wound dehiscence. The purpose of tension sutures is to redistribute the tension across the wound edges, minimizing marginal strangulation and necrosis. In horses, tension sutures are frequently indicated for closing traumatic lacerations and surgical wounds over bone plates.

Interrupted vertical mattress, horizontal mattress, quilted, and stent sutures are placed well away from the skin edges to prevent strangulation. These sutures are used to draw the

**Figure 17-5.** Appositional sutures. Refer to Table 17-4 for descriptions. (Redrawn with permission from Toombs JP, Crowe DT: Textbook of Small Animal Surgery. Philadelphia, 1993, WB Saunders.)
wound edges closer together so interrupted sutures can complete the closure without placing excessive tension on the wound margins. Subcuticular sutures are a form of tension suture because they help appose the skin edges, but they also prevent widening of the scar once the skin sutures are removed.\(^1\)

**Walking Sutures**

"Walking" sutures are buried tension sutures that move skin progressively toward the center or the opposite wound margin (Fig. 17-8). They evenly distribute tension and obliterate dead space. The skin around the wound is undermined, and, using absorbable suture material, the first bite

---

**Figure 17-6.** Inverting sutures. See Table 17-5 for description. (Redrawn with permission from Toombs JP, Crowe DT: Textbook of Small Animal Surgery. Philadelphia, 1993, WB Saunders.)
is taken deep within the dermis without penetrating the full thickness of the skin. The second bite is taken in the underlying fascia toward the center of the wound. As the suture is tied, the skin is advanced toward the center of the wound. The walking sutures are placed on each side of the wound until the skin edges meet and allow closure with simple interrupted skin sutures, placed without tension. With a skin flap, walking sutures are used to advance the flap into place. This technique prevents the formation of serum pockets subcutaneously and facilitates rapid healing and good cosmetic results in large wounds that would otherwise be managed by second-intention healing.

**STAPLES**

Advances in the development of stapling devices provide the surgeon with an alternative to hand-sutured anastomoses, ligations, and skin closures. Stapling instruments reduce tissue handling, decrease surgery time, minimize contamination, and provide secure visceral, vascular, and dermal closures when used correctly.

**Properties**

With the exception of fascia and skin staples, wound closure created by a staple instrument consists of inverted or everted

---

**Figure 17-7.** Tension sutures. Refer to Table 17-6 for descriptions. (Redrawn with permission from Toombs JP, Crowe DT: Textbook of Small Animal Surgery. Philadelphia, 1993, WB Saunders.)
layers of tissue secured by staggered double rows of B-shaped stainless steel wire staples. The staples are essentially inert and nonreactive, and they reduce the occurrence of tissue inflammation and infection. The B-shaped staple is noncrushing; however, it does compress tissue, providing some hemostasis, yet it permits nutrition of the cut edge, thereby avoiding necrosis. United States Surgical Corporation (Norwalk, Conn) and Ethicon (Summerville, NJ) developed a line of disposable instruments, making their system more convenient with reduced risk of malfunction or misuse.

Stapling Devices

Skin

Skin staples provide a rapid, precise, slightly everted skin closure, which is easily applied and more convenient than conventional suturing (Fig. 17-9, A). Each time the trigger is pressed, the instrument discharges a single rectangular staple into the skin (see Fig. 17-9, B). When the wound is healed, the clips are opened and removed with the use of a special instrument (see Fig. 17-9, C).

Ligatures

Instruments for vascular ligation are designed for application to vascular bundles that can be compressed to the dimension of 0.75×5 or 7 mm. The LDS-2 (ligate and divide stapler, United States Surgical Corporation) is clinically applicable for the rapid ligation of mesenteric vessels (Fig. 17-10, A). The instrument is pistol shaped and uses two sizes of disposable staple cartridges. When the trigger is activated, two wire ligatures are placed 1 cm apart, and a knife blade cuts between them (see Fig. 17-10, B). The instrument is used after the vessels have been isolated from their connective tissue attachments. Postoperative hemor-
Rhage may occur if the diameter restrictions recommended by the manufacturer are not followed; one author even suggests that the vascular staple should not be relied on in adult horses.21

Abdominal and Thoracic Surgery

Surgical stapling devices are commonly used in equine abdominal surgery because shortened anesthesia and surgery time and reduced abdominal contamination are critically important. The instruments are either disposable or reusable. Stainless steel and titanium staples are used in most procedures, but absorbable staples are also available. Absorbable staples and specially designed equipment is used primarily in minimally invasive surgery.

The GIA 50 Premium (gastrointestinal anastomosis, United States Surgical Corporation) is the most commonly used stapling instrument in equine abdominal surgery. It consists of two parts and uses disposable staple cartridges (Fig. 17-11, A). The cartridge fires two double, staggered rows of stainless steel staples.21 The two sets of staple lines are positioned 3.5 mm apart, and a knife blade cuts between them (see Fig. 17-11, B). One application of this instrument results in an inverting side-to-side anastomosis with a 5-cm-long stoma. It can be used for small-intestinal resection, leaving two secure blind ends that decrease the possibility of contamination by intestinal contents. The GIA is most commonly used to create an inverted side-to-side anastomosis of two hollow organs. Each fork of the GIA is inserted into the bowel lumen where it has been resected or through stab incisions. For a longer anastomosis, the GIA 80 or the ILA 100 (also by United States Surgical Corporation) may be used, providing a stoma approximately double in size. Double application of the GIA 50 in opposite directions will also accomplish this task. The stab incisions should be closed with inverting sutures. The GIA has been used successfully in the horse to perform jejunocecostomies, ileocolostomies, anastomoses of the dorsal and ventral colons, gastrojejunosotomies, small-intestinal resections with side-to-side jejunojunostomy, and functional end-to-end anastomoses.21 For a secure closure, an additional layer of sutures is often applied using a hand technique. (For details on application of these stapling devices, see Chapters 35 and 36.)
Figure 17-11. A, GIA 50 Premium stapler with disposable cartridge schematic view and nomenclature. B, The GIA 50 Premium staple cartridge contains 52 staples arranged in two double-staggered rows. The instrument's knife blade cuts between the two sets of staple lines, ending approximately 5 mm short of the last staple in the distal end. (Copyright 1974, 1980, 1988, 1998, 2005 United States Surgical, a division of Tyco Healthcare Group LP. All rights reserved. Reprinted with Permission of United States Surgical, a division of Tyco Healthcare Group LP.)

Figure 17-12. A, TA-90 Premium stapler with a disposable cartridge. B, TA-90 Premium 4.8 loading stapler contains 33 staples arranged in a double-staggered row 91.5 mm long. (Copyright 1974, 1980, 1988, 1998, 2005 United States Surgical, a division of Tyco Healthcare Group LP. All rights reserved. Reprinted with Permission of United States Surgical, a division of Tyco Healthcare Group LP.)
The TA-90 Premium (tissue anastomosis, United States Surgical Corporation) is pistol shaped and uses disposable cartridges that come in two staple sizes: 3.5 and 4.8 mm (Fig. 17-12, A). The instrument places one double, staggered row of staples 91.5 mm long21 (see Fig. 17-12, B). The 4.8-mm staple cartridges are commonly used because of the longer staple leg. The longer staples are more applicable in the thick-walled large colon of the horse. The TA-90 has been used in the horse for large colon resections22 and may be used for resections of thickened or edematous small intestine. The TA-90 is also useful for partial lung lobe resection in the horse.23 The TA-35 and TA-55 were designed for tissues of smaller dimensions. For a secure closure, frequently an additional layer of sutures is applied using a hand technique.

The EEA (end-to-end anastomosis, United States Surgical Corporation) uses disposable staple cartridges in a circular design to create an inverting end-to-end or end-to-side anastomosis (Fig. 17-13, A). The lumen of each end of the intestine to be anastomosed is tightened to the center rod of the instrument using purse-string sutures. When the intestine is properly aligned, the instrument is fired, producing a circular, double, staggered row of staples, whereas a knife blade cuts a circular stoma within the stapled ring (see Fig. 17-13, B). The EEA has limited value in equine surgery because the diameter of the stoma created by the largest EEA is not compatible with the luminal diameter of the adult equine small intestine, but it may be applicable in foals.20

TISSUE ADHESIVES

The medical use of cyanoacrylate monomers as tissue adhesives is broadening. The older, short-chain cyanoacrylates were cytotoxic; however, newer relatively nontoxic formulations are used on organ tissues. New interest in the tissue adhesives has occurred because of the formulation of the N-butyl groups. Some of the investigational uses include plastic, ophthalmic, orthopedic, vascular, otolaryngeal, and oral surgery, as well as dermal healing. Cyanoacrylates also exhibit some hemostatic and bacteriostatic properties. For example, a 2-octyl cyanoacrylate formula is available as a dermal suture replacement. It has also been used to secure mesh grafts to limb wounds with excellent results (see Chapter 25).

The use of N-butyl cyanoacrylate as a topical bandage for horses has been described.24 These cyanoacrylate bandages were functionally similar to an occlusive bandage: exuberant granulation tissue was inhibited, and the rate and type of healing on distal extremity wounds of horses were no different from conventionally pressure-bandaged limbs.

For a wound to be covered with a cyanoacrylate bandage, it must have a mature granulation bed with a smooth, dry surface. Fluid collecting beneath the bandage will disrupt a portion or all of it. Therefore, corticosteroid-based ointment or cream is applied to the mature wound surface to smooth the wound surface and decrease fluid production.25

A host of new adhesives are presently being evaluated for use on tissues (see Chapter 9). They have not been evaluated in the horse.

Drains, Bandages, and External Coaptation

CHAPTER 18

Jörg A. Auer

The application of drains, bandages, and external coaptation is an important step in state-of-the-art wound management. The different dressings used in association with bandages are discussed in Chapter 26.

DRAINS AND DRAINAGE

History

Hippocrates, in the 4th century BC, was the first to use drains, in the form of hollow tubes, to treat empyemas. In the 2nd century AD, Celsius and Galen used conical tubes of brass and lead to drain ascites, and these devices were used for 1500 years. In 1719, Heisler introduced capillary drainage via a gauze wick inside a metal tube. In 1859, Penrose used soft rubber tubing as a drain, known today as the Penrose drain. Kehrer modified this technique in 1882 by placing gauze tubing as a drain, known today as the Penrose drain. Today's version of the cigarette drain consists of semirigid vinyl or polyvinyl tubing inserted into a drain: (1) to facilitate elimination of dead space, (2) to evacuate existing fluid and gas accumulations, and (3) negative pressure was subsequently applied to the semirigid tubes to provide an active system, and finally Raffle developed the technique of continuous suction in 1952.

PURPOSES

Drains are implants designed to channel unwanted fluids such as wound secretions, purulent material, bile, urine, blood, or gases out of the body. Proper use of drains generally speeds up healing time, whereas inappropriate use usually delays healing, occasionally even increasing morbidity and mortality. There are three reasons to place a drain: (1) to facilitate elimination of dead space, (2) to evacuate existing fluid and gas accumulations, and (3) to drain ascites, and these devices were used for 1500 years. In 1719, Heisler introduced capillary drainage via a gauze wick inside a metal tube. In 1859, Penrose used soft rubber tubing as a drain, known today as the Penrose drain. DRAINS AND DRAINAGE

History

Hippocrates, in the 4th century BC, was the first to use drains, in the form of hollow tubes, to treat empyemas. In the 2nd century AD, Celsus and Galen used conical tubes of brass and lead to drain ascites, and these devices were used for 1500 years. In 1719, Heisler introduced capillary drainage via a gauge wick inside a metal tube. In 1859, Penrose used soft rubber tubing as a drain, known today as the Penrose drain. Kehrer modified this technique in 1882 by placing gauze inside the Penrose drain to facilitate drainage, thus creating the “cigarette drain.” Today’s version of the cigarette drain consists of semirigid vinyl or polyvinyl tubing inserted into a Penrose drain to prevent soft tissue obstruction and increase capillary action. All of these drains were applied in a passive system, allowing gravity, capillary action, natural pressure gradients, or overflow to control fluid and gas flow. Negative pressure was subsequently applied to the semirigid tubes to provide an active system, and finally Raffle developed the technique of continuous suction in 1952.

PURPOSES

Drains are implants designed to channel unwanted fluids such as wound secretions, purulent material, bile, urine, blood, or gases out of the body. Proper use of drains generally speeds up healing time, whereas inappropriate use usually delays healing, occasionally even increasing morbidity and mortality. There are three reasons to place a drain: (1) to facilitate elimination of dead space, (2) to evacuate existing fluid and gas accumulations, and (3)....
to prevent anticipated formation of fluid collections. Understanding the principles of drain selection, placement, and management minimizes the risks associated with these implants.

**Materials**

The ideal drain is inert, soft, nonreactive, and radio-opaque. Table 18-1 lists common drain types and materials. Soft latex is frequently used in drains; it allows excellent passive drainage of wound fluids. Because it is pliant and does not maintain a rigid lumen, it fits comfortably within the wound. Polyvinylchloride (PVC) drain tubes provide excellent wound fluid evacuation, especially from body cavities and deep surgical wounds. They are less flexible than latex and have a rigid lumen, allowing them to be used for passive or active systems. Frequently, PVC drains are multifetened to permit fluids to exit the wound or body. Other drains are manufactured out of silicone, an organic compound in which all or part of the carbon has been replaced by silicon (a nonmetallic element occurring in nature as silica). Silastic is the trade name for polymeric silicone substances having the properties of rubber; it is biologically inert and frequently used in applications other than drains. It is softer than PVC, but at some diameters it maintains a rigid lumen. Therefore, Silastic can be used for active or passive drainage systems. The compliance of the material increases the animal’s comfort and makes this type of drain ideal for placement in sensitive areas and within small spaces.

**Placement**

The basic principles of wound management, such as clipping of the hair, aseptic preparation of the implantation site, and possibly local anesthesia, are considerations when placing a drain. In sterile wounds, the drain should be applied under aseptic conditions. Additionally, this sterile environment should be maintained as long as possible through covering of the wound and frequent bandage changes. Passive drains should exit below the most ventral aspect of the wound or dead space.

The drains should be placed into the space requiring the most drainage. Occasionally, several drains are needed to evacuate a large area or several different tissue layers. The shortest and most direct avenue for evacuation of secretions should be selected. Drains cause some mechanical injury and therefore should not be placed in the immediate vicinity of blood vessels, nerves, and suture lines. To reduce the risk of suture dehiscence, drains should exit through separate incisions, away from the suture line (Fig. 18-1, A). It is important to secure the drains with individual sutures to prevent their loss into or out of the wound. A suture is placed from the skin into the wound, through the drain, and back through the skin, where it is tied (see Fig. 18-1, B). The suture used for the drain should be easily distinguishable from the skin sutures to avoid inadvertent premature removal of a suture securing the incision. If a drain is placed into a wound that is to be closed, care should be taken to avoid inadvertent incorporation of the drain into the suture line, because drains are usually removed before incisional sutures (see later). The drain end should be long enough to prevent its disappearance into the wound and to evacuate drainage fluids. It is also important to protect the drains from attempts by the patient to remove them. Large openings provide better and longer-lasting drainage. Small exit incisions frequently plug up, even with a drain in place, preventing evacuation of drainage material.

**Management**

The amount of drainage and its consistency dictate the frequency that bandages need to be changed or vacuum containers emptied. The exit site should be cleaned with antiseptic solutions at every bandage change. If a passive drain is used, it is advisable to protect the adjacent skin from irritation by covering it with a thin layer of Vaseline. Passive drains should seldom if ever be back-flushed, and active drains should not be back-flushed unless obstructed because of the risk of transporting microorganisms into the wound. Additionally, healing may be interrupted by the mechanical disturbance of flushing.

Re-establishing drainage in an obstructed drain exit wound should be performed carefully. If the drain exit site is obstructed, it should be reopened. First the site is prepared for aseptic surgery, followed by insertion of a sterile hemostatic forceps into the opening and gentle spreading of its jaws to separate the wound ends.

**Removal**

As a general rule, drains should be removed as quickly as possible. An average time for maintaining drains is 2 to 4 days, the duration of the débridement period of wound healing. However, there are exceptions to this rule:

1. When evacuating blood from small cavities, the drain may be removed after approximately 24 hours.
2. When treating bacterial infections, the drain should be maintained for 48 to 72 hours.
3. If large dead spaces remain, as after tumor removal, the presence of a drain may be necessary for as long as 2 weeks.

The best indicator for drain removal is an abrupt decrease in the drainage volume and a change in its characteristics to a serous, non-odiferous, slightly turbid fluid. Because drains are foreign material, they induce the production of secretions. At the time of drain removal, exit sites are prepared for aseptic surgery. While the proximal end is held in place, the distal securing suture is removed, followed by application of slight tension to the distal end of the drain, before it is cut off at skin level. This ensures that the contaminated external part of the drain is not pulled through the wound bed, possibly recontaminating it. The proximal suture is removed, and the rest of the drain is pulled out of the wound bed. The two incisions are left to heal by secondary intention. In case of only one exit portal present, the securing suture(s) is (are) cut and the drain is removed through the distal portal.

If gauze packs are used as tamponade in a bleeding wound, they are removed in stages, with a portion withdrawn and cut off daily, each time leaving a protruding stump to facilitate removal of the next portion.

Complications
Foreign body response and ascending infection are the most common complications associated with drain use. Because drains are foreign bodies, an adverse response to the drain cannot be avoided. If a portion of the drain is accidentally left in the wound, wound drainage will persist until it is removed. Therefore, the removed drain should be carefully examined to verify complete removal. Ascending infection may aggravate an already existing infection, and the microorganisms in the wound may be resistant to previously used antibiotics. Cultures should be obtained if the character of the wound fluid changes or the volume increases while a drain is in place.

Loss of function may be encountered, especially if the distal exiting portal is too small. It is therefore advisable to initially remove a triangle of skin and subcutaneous tissues at the exiting portal. Another cause of loss of function is the kinking of a tube drain, effectively obliterating the drain lumen. Repositioning of the drain and gentle traction frequently restores function.

Suture dehiscence is an occasional complication that may be attributed to the placement of a drain. Also, vessels and nerves may be damaged during drain placement through stab incisions and blind implantation. Rigid drain tubes may cause pain if they are located near osseous protuberances.

Types of Drains
Drain selection depends on the wound and on expected activity level of the patient. Additionally, the preferences of the surgeon, based on experience, play an important role in the selection of a drain.

Passive Drains
GAUZE DRAINS
Gauze drains are prepared from gauze rolls or gauze sponges. They may be soaked with an antibiotic or even with an antiseptic. The antibiotic may be added at the time of drain placement, or the gauze may come commercially prepared (Fig. 18-2, and see Table 18-1). If a large amount of gauze is used to pack a cavity, several rolls are tied together securely to ensure that eventually they are completely removed. Drainage occurs by gravity and capillary action.

Gauze drains are applied as packing in profusely bleeding cavities (e.g., after nasal septum removal) or in abscesses that cannot be drained at the lowest point. They can be used to evacuate a hematoma (after closed castration). In Europe, gauze drains are frequently attached to the stump of the spermatic cord after castration to facilitate drainage and prevent fluid accumulation in the scrotum. The advantages of gauze drains include cost effectiveness and ease of removal in stages. The adherence of fibrin clots to the gauze is a disadvantage, as it may result in bleeding after removal.

PENROSE DRAINS
Penrose drains are the most commonly used drains because they are soft, pliable, easily sterilized, readily available, and economical, and they cause little foreign body reaction (see Table 18-1). They are available in lengths from 30 to 45 cm (12 to 18 inches) and in widths from 6 to 25 mm (1/4 to 1 inch) (see Fig. 18-2). Most drainage occurs extraluminally and is driven by gravity and capillary action. To facilitate intraluminal drainage, the drain may be installed inside the body at its most proximal aspect or fenestrated. However,
despite providing access of drainage to the inside of drain, fenestrations reduce the surface area, which decreases their efficacy. Also, the fenestrations weaken the drain and may result in breakage and the risk of subsequent incomplete removal if adhesions between the drain and the soft tissues develop. Penrose drains can be successfully used in wounds that cannot be completely débrided and in the presence of residual foreign material, massively contaminated tissue, questionably viable tissue, and fluid-filled dead spaces. Additionally, these drains have been applied with good results underneath skin grafts, in open wounds left to heal by secondary intention, and even in septic joints and tendon sheaths left open for lavage. Penrose drains are not suitable for use with suction (because they collapse under a vacuum), in the abdominal cavity (because they are walled off within a short time in the abdomen), or in the thoracic cavity (because they allow air to pass into the thorax).

**Sheet Drains**
Frequently, large wounds over muscular areas have to be drained. In these instances, several drains are needed to effectively drain the entire wound. An alternative is the sheet drain (see Fig. 18-2 and Table 18-1), which is made of red rubber and has a cross-section shaped like a sine wave. The sheet can be trimmed to the desired size. To facilitate additional space in the field to be drained, the sheet can be folded over. Because of its inherent stiffness, there is a gap between the two layers of drain when folded, which resists obstruction. These drains are left in place only a couple of days, but they work efficiently during that time. Red rubber generally induces a significant foreign body reaction.

**Tube Drains**
Tube drains differ in form and material. They can be relatively stiff, single tubes of red rubber, contain a cross-sectional wave pattern, be of soft, pliable, ribbed, flat Silastic, or they can be tubular silicone drains that consist of 12 single tubes joined together, each with a diameter of 3 mm (Fig. 18-3, and see Table 18-1). These drains function by extraluminal and intraluminal flow and have been successfully applied for draining fluid from wounds as well as from the abdomen and thorax. The more rigid drains have a tendency to induce a greater tissue irritation than Penrose-type drains. Simple tube drains provide only weak capillary action but they are effective for gravity drainage. The outer and inner surfaces of the tubes should exhibit a low coefficient of friction to facilitate evacuation of blood clots as well as their own removal. Some of the drains can be connected to a suction apparatus to evacuate fluids without collapsing and to allow irrigation. These drains are inexpensive and readily available, and they cause less interference with tissue healing than Penrose drains.

One disadvantage of tube drains in a passive system is that they are easily obstructed by debris, so they become ineffective until they are back-flushed to make them patent again, and this may occur frequently. Therefore, their use is limited to grossly contaminated areas where bacterial contamination by back-flushing is not too worrisome. Some materials (such as red rubber) induce greater inflammatory reactions than others (such as PVC or Silastic). Polyethylene contains certain impurities that support bacterial growth.

When used intra-abdominally, omentum can easily obstruct tube drains.

**Active Drains**
**Closed Suction Systems**
In equine practice, simple tube drains attached to a suction apparatus providing either intermittent or continuous suction are frequently used in infected joints; in large, deep wounds; to evacuate the pleural space; and under full-thickness skin grafts. Blake and fenestrated tube drains are often used in these situations (Fig. 18-4), and occasionally Snyder Hemovac drains are used (Fig. 18-5, see Table 18-1). Either the end of the drain is multifenestrated or the cross-section consists of a modified cloverleaf pattern with four slits and protected spaces (as in the Blake drain). The external end is made of smooth tubing and is connected through a three-way stopcock, most frequently to a syringe; the plunger of the syringe is withdrawn to achieve the desired negative pressure, and it can be held in that position by introducing a large needle or a small pin across the plunger and resting it on the syringe end (see Fig. 18-5). This provides the most economical suction apparatus. The three-way stopcock allows interruption of the suction action prior to removing the syringe for emptying. This is also an effective means to fight against ascending infection. A study comparing Penrose drains to closed suction drains showed that at 24 hours, 34% of the Penrose drains were contam-
inated compared with none of the closed suction drains.2,4,7

If suction is applied in a continuous manner, soft tissues can rapidly occlude the drain. High negative pressure may cause injury to tissues, and if the system is suddenly disrupted, reflux of evacuated fluid may occur, increasing the risk of infection. The installation of a Heimlich valve into a suction system can prevent reflux of fluid (Fig. 18-6).

A special closed suction system has been used in humans to promote granulation tissue production in large open wounds, especially when there is bone involvement. This device has been successfully applied in horses. The wound to be treated by suction is prepared for aseptic surgery and the wound edges are clipped and trimmed. A sponge is cut to slightly overlap the wound size. The continuous suction device is installed into the sponge. The entire sponge and the suction device are covered by a special adhesive tape, which provides an airtight seal between the wound and the normal skin (Fig. 18-7). A bandage is applied to protect the device and maintain external pressure. When suction is applied, the evacuated fluid accumulates in a container. Movements of the horse must be restricted to ensure continuous suction. This method of wound treatment can change an infected, odiferous wound into one covered with healthy granulation tissue within 4 days (Fig. 18-8).

OPEN SUCTION SYSTEMS
Open suction is infrequently applied in equine medicine. One system involves a sump drain, which is a large drain tube with a second, smaller tube in the wall or within the lumen of the larger tube. This "vented" suction apparatus allows the entrance of air to the wound through the narrow lumen tube while debris and fluid are evacuated through the larger tube. Suction may be applied in continuous or intermittent form.4,7 The airflow improves drainage and decreases the risk of occlusion. However, sump drains do not adapt well to many veterinary hospital situations. Large, portable, or built-in wall units are needed. Also, the large...
quantities of air needed to keep the suction end open may increase the risk of infection and tissue irritation. Bacterial filters over the air inlets have been shown to effectively reduce infection rates.2

The application of a Heimlich valve provides an effective barrier to ascending infection in open drainage of body cavities. This device prevents inflow of air but facilitates drainage of fluid and debris (see Fig. 18-6).

Drainage of Body Spaces

Drains in Synovial Spaces

Removal of purulent debris from synovial spaces is facilitated by drain placement. Passive or active drainage systems can be employed for this purpose, but the passive Penrose drains are best. It is important that they be placed in the distal dependent aspect of the synovial space and maintained beneath a sterile bandage. Conversely, active drainage systems can be uncomfortable and abrasive to articular cartilage and tendons because of the rigidity of the material. However, Jackson-Pratt drains, made from Silastic, are multifenestrated and can be placed in these small spaces to provide efficient active drainage.8

Drains in Body Cavities

ABDOMEN

Passive drainage of the abdominal cavity requires dependent placement of a rigid-lumen drain tube.7 PVC and Silastic drains can be used effectively for this purpose. (Penrose drains are not functional for this purpose, and should not be used.) Intraoperative placement of multifenestrated drains should be considered after abdominal lavage, or when large volumes of exudate or transudate are expected. The drain is placed in a dependent position away from the abdominal incision and sutured to the skin to prevent dislodgement. A sharp trocar with a threaded end is provided to place the drain (see Fig. 18-4). It is important to use the trocar to prepare the drain exit portal so that it is just large enough to allow drainage to occur through the drain lumen but not around it. An exit wound that is too large may allow evagination of omentum through it. Bandage placement over abdominal drains is impractical because of the drainage volume obtained. The drain should be removed as soon as drainage slows or ceases. Protecting the drain end is important to prevent ascending infection. A simple method to reduce this risk is to cut off the end of a latex condom, or a finger from a surgical glove, and to place it over the drain, where it acts as a one-way valve. Such valves are commercially available under the name of Heimlich valves (see Fig. 18-6).

Thoracic trocars made from PVC and Silastic can be placed percutaneously for drainage of air, urine, exudates, or lavage fluid from the abdominal cavity. Functional time may be limited by the number of fenestrations in the commercial products, so it is helpful to provide additional fenestrations. Squares holes in the drain may provide better drainage than round holes.4 To place the drain, a dependent position is identified. If a longstanding peritonitis is present, or if there has been previous surgery, ultrasonographic guidance may be indicated to identify bowel adhered to the body wall. The site is prepared for aseptic surgery, and local anesthetic is infiltrated. A 1-cm incision is made through the skin and the external rectus sheath. An appropriate-diameter thoracic
trocar is selected (16-30 Fr), and carefully inserted through the rectus abdominis muscle, internal rectus sheath, and peritoneum. When the abdominal cavity is penetrated, the obturator is removed, minimizing the risk of inadvertent bowel puncture. The drain is subsequently positioned properly and secured. Drains can be sutured to the skin in a variety of patterns. Two useful patterns are the "Chinese finger trap" suture and the "double clove hitch" pattern9 (Fig. 18-9). If the drain is left in place, the drain end is protected as previously described, or a Heimlich valve may be added.

In cases that benefit from open peritoneal drainage, polypropylene mesh can be used to provide drainage over several days.7 After correction of the primary problem, the mesh is secured into the abdominal closure with sutures, leaving a gap for fluids to escape. The mesh is left in place until drainage subsides, and it is removed during a second surgical procedure (Fig. 18-10).

THORAX
Thoracic drainage presents special problems because negative pressure needs to be maintained in the chest despite the frequent presence of air. The use of a rigid drain tube is necessary. Removal of air can be achieved through active or passive mechanisms. To place a drain for removal of air, a dorsal site is selected and prepared for aseptic surgery. Local anesthetic is infiltrated prior to establishing a 1-cm stab incision through the skin. A thoracic trocar is inserted and tunneled cranially for one or two rib spaces and inserted into the thorax along the cranial edge of the rib, avoiding the intercostal vessels located on the caudal border of the rib (Fig. 18-11). Once the thorax has been penetrated, a Heimlich valve is placed on the drain end. The Heimlich valve has a rubber liner, which allows air to exit during expiration, and it collapsing on inspiration, restricting backflow of air (see Fig. 18-6). If a large volume of air is present, suction can be applied to the open end of the Heimlich valve, rapidly removing air and reestablishing negative pressure. The drain is secured by one of the means previously described. If the primary problem is corrected, the drain can usually be removed in 24 hours.

Removal of fluid from the thorax is best achieved using an active drainage system. Multifenestrated PVC drains surgically placed, or thoracic trocars percutaneously placed, are suitable for this purpose. A closed suction device is applied to the catheter and maintained until drainage subsides. It is

**Figure 18-10.** Polypropylene mesh used for open peritoneal drainage. The mesh, seen interposed between the wound edges, is ready for removal.

**Figure 18-11.** Proper placement of thoracic drains. A drain in the dorsal thorax is placed with a Heimlich valve (Heimlich chest drain valve, Bard Parker, Becton Dickinson, Inc, Lincoln Park, NJ) to prevent the backflow of air. A ventral drain uses a syringe-adapted closed-suction device to provide safe removal of fluid accumulating in the ventral thoracic cavity.
important that the closed suction device not become dislodged from the drain, as this would cause a rapid loss of negative pressure and introduce environmental contaminants into the thorax (see Fig. 18-11).

**BANDAGES**

Bandages are applied to cover wounds protected by dressings, to prevent edema formation after injuries of the limb, and to support the limb in conjunction with an added splint in the case of a fracture of a bone. The type of bandage is chosen on the basis of the location and the nature of the injury.

**Foot Bandage**

Foot bandages are applied to manage a variety of problems. Part of a roll of cotton is placed over a primary wound dressing (Fig. 18-12). The padding is secured with gauze, and it can be held in place with either cohesive or adhesive bandaging tape. Duct tape placed over the bottom of the bandage will render the bandage more durable and less permeable to urine and water (see Fig. 18-12). Moisture can be controlled from entering the bandage by placing plastic over the foot. An empty 5-L fluid-bag can be opened with a pair of scissors and placed over the hoof capsule and fastened with adhesive tape, attaching it effectively to the foot. This type of bandage is useful if it is desirable to exclude water from the wound environment, when a poultice or soak is applied to the foot, or when preparing a foot or pastern for any type of surgery.

**Lower Limb Bandage**

A lower limb bandage is applied from the bulbs of the heel up to just below the carpus or tarsus. It usually consists of a roll of cotton, applied in the standard clockwise fashion (pulling the tendons to the inside) (Fig. 18-13). The thickness, or number of layers, of the bandage is dictated by the underlying medical problem. Each layer is secured with conforming roll gauze, wrapped snugly in a spiral pattern, overlapping half the tape width, to prevent the padding from slipping or bunching. The gauze is overlaid with either adhesive or cohesive bandaging tape securing the bandage in position. A single wrap of adhesive tape around the bottom of the hoof and the top of the bandage prevents

---

**Figure 18-12.** A, Several layers of folded-up cotton are placed over the sole of the foot. B and C, The roll of cotton is subsequently applied in several layers over the foot and fetlock area. D, A roll of elastic adhesive tape, tightly applied, finishes the bandage. E, Some protection may be applied to the sole to prevent wearing of the bandage. If deemed necessary, the bandage may also be covered with several layers of casting tape to further reduce motion in this region and to stabilize an injury of the bulbs of the heel.
bedding materials from gaining access to the underlying skin or wound respectively. Care should be taken to extend the bandage to the level of the carpometacarpal or tarsometatarsal joint, to prevent inadvertent tendon damage if a considerable amount of tension is applied to the elastic bandage tape. At the level of those joints, the tendons are lodged between the vestigial metacarpal bones, which provide protection. Additionally, the coronary band should be included in the bandage so that tape can be applied directly to the hoof capsule.

**Full Limb Bandage—Forelimb**

A full limb bandage is applied from the bulbs of the heel up to the elbow region (Fig. 18-14). When applying a full limb bandage, movement of the carpus requires that special
attention be given to this area to prevent decubital ulcers. The bandage is usually “stacked” to prevent slippage and subsequent irritation over bony prominences. Padding materials are the same as for the lower limb bandage and therefore require placement in two stages. The distal bandage is initially applied as previously described. The proximal part is subsequently added on top of the lower limb bandage, overlapping it for 5 to 10 cm. Applying a doughnut-shaped cotton ring or incising the gauze over the accessory carpal bone helps prevent skin irritation over that area and potential development of skin ulcers. Tightening of the bandage in layers provides more stability and increases the support. If the bandage becomes displaced distally, it is imperative that it be changed at once to prevent skin ulcers from developing over bony prominences.

Full Limb Bandage—Hindlimb
Motion of the tarsus requires special attention when applying a bandage to that region. Primary wound dressings are held in place using gauze applied in a figure-eight (Fig. 18-15). The crossing of the “8” occurs over the dorsal aspect of the tarsus, with the loops applied around the proximal metatarsus and the distal tibia of the limb, leaving the point of the hock open. Caution should be used in applying tension over the gastrocnemius tendon. The bandage is also applied in two steps, as described for the forelimb. The proximal part of the bandage overlaps the distal bandage. Applying soft cotton patches medially and laterally between the tibia and the gastrocnemius tendon provides support and reduces the pressure of the latter, thereby serving as protection against tendon damage that could result from excessive tension. Each layer of padding material is first secured with gauze, applied at a right angle to the limb, as opposed to the figure-eight for the primary dressing. Application of cohesive or adhesive tape completes the bandage (see Fig. 18-15). The bandage is finished by applying elastic adhesive tape around the hoof capsule below, and to the skin on top of the proximal end of the bandage to prevent access of bedding to the skin underneath the bandage.

The application of a full limb bandage to the hind limb decreases the movement of all joints in the limb because of the reciprocal apparatus. Some horses have more problems coping with this situation, especially when gaining or rising from recumbency. Therefore, the patient will need to be observed after such a bandage is applied.

Splints
A special type of full limb bandage is the Robert Jones dressing (RJD), for which several layers of cotton are evenly applied over the entire limb, each layer tightened separately with elastic nonadhesive tape. The final cover of the RJD consists of a layer of tightly applied elastic adhesive tape. The size of the RJD should be approximately double the size of the limb and produce a dampened “ping” when snapped with the finger on the outside. This type of bandage provides good support to a severely injured or fractured extremity, because it adds rigidity, especially if a splint of some kind is incorporated into the bandage. An RJD with an incorporated splint allows weight bearing on a fractured limb.
Splints must be applied carefully to prevent decubitus ulcers. Splints are commonly made from wood, PVC pipe, or metal, or they can be assembled from cast material incorporated into the bandage. Wood splints are not ideal because they lack strength in small conforming widths, and larger boards do not conform well to the limb. This limitation is overcome by incorporating several small-width slats into the bandage. The sum of the slats used increases the bandage rigidity and achieves the desired result. With adequate padding in place, 1×4-inch (2.5×10-cm) boards can be incorporated into a bandage and arranged in at least two right-angle planes. Board splints should extend from the hoof to the joint proximal to the affected area in at least one plane. If the radius or tibia is to be immobilized, a padded lateral splint extending beyond the top of the bandage should be incorporated to prevent adduction of the limb (see Fig. 18-15).

Excellent rigidity can be achieved by using PVC pipe as splints. The diameter of the schedule 40 PVC pipe selected depends on the size and location of the limb to which it is applied. The material should be cut longitudinally in two or three sections. The splint may be modified by removing half-moon–shaped portions at strategic locations to allow access to regions with a wider diameter, such as the carpus. A good compromise has to be found between the PVC pipe diameter and the diameter of the widest part of the limb to be incorporated into the splint.

Neither PVC pipe nor wood conforms well to the limb, however. Casting tape, on the other hand, conforms well to the bandaged limb, but it does not provide the bandage rigidity that can be achieved with wood or PVC pipe. Splints may be made from casting tape rolls, or purchased in that configuration as a longuette. Addition of a casting tape splint reduces the amount of padding needed while providing suitable immobilization in most circumstances. Casting tape splints cannot be applied to extend to the shoulder or hip to prevent adduction of the limb for immobilization of the antebrachium or crus, respectively.

Stainless steel splints are commercially available for temporary immobilization of the distal limb, including the metacarpus in the forelimb. These splints are used as emergency fixation for breakdown injuries of the suspensory apparatus, for flexor tendon injuries, for fractures of the metacarpal condyle, and for phalangeal fractures when a strut of bone remains to support the limb. They are especially useful for transport of horses with such injuries (see Chapter 78).

**EXTERNAL COAPTATION (CASTS)**

**Cast Application**

**Materials**

Historically, plaster of Paris casts have been popular for external coaptation. Plaster is still a viable casting material, because it is easy to apply, has good molding capability, and is inexpensive. Unfortunately, plaster casts also are heavy, disintegrate when wet, and do not allow exchange of air, which makes this type of cast uncomfortable when worn for a prolonged period. Furthermore, plaster is not as strong as fiberglass and thus requires more material to prevent breakage. This results in a heavier cast.

The shortcomings of early fiberglass casts were corrected and they are now made with materials of superior quality; they are lightweight, strong, and radiolucent, and they have excellent molding capability. Additionally, the porosity of the material allows exchange of air across the cast. Although these types of casts are more expensive than plaster casts, they are more durable and require less material for adequate strength. A variety of fiberglass casting materials are presently available on the market. Twenty years ago, the mechanical properties of several of these materials were compared, and differences were seen. However, since then major improvements in handling ability and strength were implemented. For practical purposes today, there are no significant differences between the products on the market.

The strength of a cast is determined mainly through bonding between the tape layers, so swift cast application is of great importance for a strong cast. Fiberglass casts are about 20 times stronger and 4 times lighter than plaster casts. All cast materials exhibit an exothermic reaction (i.e., they release heat) during setting; the more layers applied, the greater the reaction. Immersion in water hotter than 27°C (80.6 °F) immediately before application also results in heat production. However, warm water reduces the curing time considerably. Therefore, veterinarians inexperienced in the application of casts should use cool water, which permits a longer application time but ensures that all tape layers will bond together as the cast hardens. Unlike in the procedure for application of plaster casts, water should not be expressed from the fiberglass material before application, because the cooling effect of the water is lost. Also, freshly applied casts should not be covered with bandage materials before they have set. The casts usually set within 4 to 5 minutes and allow weight bearing within 20 to 30 minutes.

**Indications**

External coaptation by casting is indicated in selected fractures of the phalanges, as adjunct treatment to internal fixation of fractures, for immobilization after tendon repair, and to stabilize wound healing in regions of continuous motion, such as heel lacerations (see Chapter 93). Casts are also applied to protect a limb during recovery from anesthesia—for example, after repair of a condylar fracture of the distal MCIII/MTIII. Tube casts may be applied to foals with incomplete ossification of the cuboidal carpal and tarsal bones to facilitate ossification while weight is distributed evenly across the joints (see Chapter 89).

**Technique**

Most casts are applied with the horse under general anesthesia. This prevents the animal from moving during the application and setting of the cast, which may weaken the cast or cause pressure points, with subsequent development of decubitus ulcers. However, with adequate sedation, casts can also be successfully applied in standing horses.

Before starting, all materials should be laid out for efficient and swift cast application. The entire portion of the limb to be covered with a cast should be cleaned and dried. It is not advisable to clip the hair unless that is required for a surgical procedure. Special attention should be given to the hoof. It should be trimmed and all excessive sole and...
frog material removed. It is advisable to paint the sole and frog with a solution containing iodine. Any lacerations or wounds should be debrided, sutured if necessary, and covered with a sterile nonadhering dressing. This dressing should be secured by a gauze or elastic bandage. It is advisable to apply boric acid to the portion of the limb that will be covered with a cast. Boric acid is a drying agent with antibacterial properties. A zinc-containing soft gauze is an alternative, providing protective properties to the skin. A piece of stockinette somewhat longer than twice the proposed length of the cast is prepared by rolling it from each end toward its center. One side is rolled outward and the other side inward (Fig. 18-16). For foals, a 5.0-cm (2-inch)-diameter stockinette should be selected. A 7.5- or 10.0-cm (3- to 4-inch) stockinette is adequate for adult horses. The stockinette should be neither too loose nor too light.

The stockinette is applied to the limb by an outward unrolling of the previously rolled portion (see Fig. 18-16). Once the first layer of stockinette is applied, it should be pulled distally for about 2 cm (½ inch) to ensure normal alignment of the hair on the limb. The other half of the stockinette is then twisted at the sole region and unrolled like the first half. At this stage, the stockinette should extend about 5 to 10 cm (2 to 4 inches) past the proximal end of the cast. Generally, a ring of orthopedic felt, about 7 cm (3 inches) wide, is applied to the most proximal aspect of the cast between the two layers of the stockinette (see Fig. 18-16). This ring of felt should not be overlapped but should be adjusted to the correct length to perfectly appose both ends. The ends are held in place temporarily by nonelastic adhesive tape.

For plaster casts, a cotton stockinette usually is used, whereas synthetic stockinettes are preferred for fiberglass casts. Because synthetic stockinette is manufactured from acrylic fiber that has little capacity to hold moisture, moisture is transferred away from the body. Also, synthetic stockinette maintains greater bulk, adding to the padding. Some clinicians prefer to add a thin layer of synthetic cast padding between the two layers of stockinette. Additional attention should be given to potential pressure points, such as over the accessory carpal bone, ergot, or calcaneus regions. Extra padding, consisting of a silicone doughnut or orthopedic felt with an elliptic hole, should be applied to these areas. After the stockinette and padding have been applied, the limb should be positioned for application of the cast. In most cases, the limb should be extended with the metacarpal and phalangeal regions in the same frontal plane. In special cases, it may be preferable to cast the limb in a normal weight-bearing position. For this purpose, the carpus is flexed and slight pressure is applied either to the dorsum at the fetlock region or to the sole in a dorsal direction (Fig. 18-17). An assistant must hold the limb in the desired position. The palm of the hand, not the fingertips, should be used to apply pressure to a specific region and thereby help prevent pressure point development.

The polyurethane, resin-impregnated foam introduced in the early 1990s is an efficient means to reduce cast sores. This material is immersed in warm water for about 1 minute. After minimal squeezing, the soft foam is applied evenly over the stockinette. Care is taken to overlap each turn-half of the width, with the result that a double layer of foam is applied over the part of the limb being covered with a cast. Minimal tension is applied. Wearing gloves during application of the foam is strongly encouraged.

To facilitate cast removal under practice conditions, a Gigli wire attached to a long felt strip (Fig. 18-18, A) may be placed medially and laterally over the padded limb (see Fig. 18-18, B). The wire should be long enough that some excess wire protrudes proximally and distally. Once the cast is finished, the excess wire is rolled up and placed underneath the elastic tape applied to this region (see Fig. 18-18, C).

Latex gloves must be worn for application of a fiberglass cast. The airtight packages of the fiberglass tape are opened immediately before application. The fiberglass tape is held with both hands, separating the free end from the rest of the material, before submerging it in the water. The fiberglass tape is held in water at about 21° to 27° C (70° to 80° F) for 5 seconds. During this time, the tape is squeezed four or five times to encourage complete penetration by water. The fiberglass tape is removed from the water dripping wet and immediately applied to the limb. Cast application is started at the foot and progresses in a proximal direction, overlapping at least half the width of the roll until the most proximal aspect is reached. After applying two layers at the
top, the cast material is directed distally and applied evenly over the limb. As a rule, the cast bandages are applied in progression by continuing with the next bandage where the previous one ended. Changing direction during cast application is done by folding the cast material at one place and smoothing out the fold with the flattened hand. The newer materials adapt so well that in most cases directional changes can be carried out without folding the material over. Care should be taken to follow the contours of the limb and not to apply too much tension to the tape, which could interfere with circulation.

After the first few layers of cast material are applied, the extra stockinette extending on top of the cast is folded distally and covered by the following layers (see Fig. 18-17). fiberglass cast material is applied until the cast reaches a thickness of 7 to 8 mm (1/4 to 1/2 inch) throughout the total length of the cast. This requires four to six rolls of 12.7-cm (5-inch) fiberglass casting tape for a half-length cast and 10 to 12 rolls for a full-length cast.

If deemed necessary, a straight splint in the shape of an old hoof rasp or any similar type of material may be incorporated into the cast on its dorsal aspect (see Fig. 18-17). This splint should be covered with cast material to prevent accidental trauma to another limb. Such a splint would reduce the amount of cast material needed for a weight-bearing cast.

Once sufficient cast material is applied, the cast is molded over its total length and the surface smoothed out. It is important not to flex the joints under the cast from the time cast application begins until the cast has set. Most casts harden within 5 to 7 minutes after the final roll is applied.

If the limb is cast in an extended position, a wedge should be incorporated in the cast under the heel (see Fig. 18-17). The wedge permits weight to be applied over a greater surface than just at the toe. It is advisable to protect the sole with a layer of hoof acrylic, a piece of old inner tube, or the bottom of a gallon plastic bottle, taped to the foot with nonelastic tape.
Figure 18-18. A, Two pieces of Gigli wire are attached to felt strips. The two ends are rolled up. B, The felt strips with the wire are applied medially and laterally to the padded limb. C, The cast is applied in routine fashion. The rolled-up ends of the wire are covered with tape at the end of cast application. D, At the time of cast removal, the ends of the wire are attached to the handles, and by slow sawing movements, the medial and lateral sides of the cast are severed apart. Finally, the two shells still connected at the sole are split dorsally and palmarly, allowing the limb to be removed from the cast. (Photos courtesy C. Lischer, Zurich.)
To prevent foreign material, such as wood shavings or straw, from entering at the top of the cast and causing irritation, a collar of adhesive elastic tape should be placed around the top of the cast and continued about 6 cm (2 1/2 inches) proximally up the limb.

Casts applied with the limb in extension result in a longer limb than the ipsilateral counterpart. Therefore, the cast limb is usually held in an extended or non-weight-bearing position. This may lead to continuous overload of the good limb, which increases the risk of foundering. It is advisable to tape a rubber pad to the ipsilateral foot and in so doing to lengthen it as well, preferably to the same extent as the cast limb. This comforts the patient and facilitates even weight bearing.

Generally, hindlimb casts are applied in the same way as casts for the forelimb. The most likely areas for pressure sore development are the Achilles tendon and the dorsal aspect of the tarsus. The tarsal region presents an additional problem in a full-leg hind limb cast because of the reciprocal apparatus. Attempts of the horse to flex the hind limb in a full limb cast may cause the peroneus tertius tendon to avulse from its attachment or rupture in the tarsal region, allowing flexion of the stifle without flexion of the tarsus. Treatment of this problem is discussed in Chapter 99.

Exercise should be limited for a horse with a cast. It is preferable to keep the horse in a cool environment to prevent excessive sweating under the cast. In this respect, fiberglass casts are superior to plaster casts because fiberglass casts are porous and dissipate heat from the body.

It is advisable to palpate the cast every day, especially over possible pressure points. A localized area of increased heat, palpable through the cast, is an early sign of a developing skin ulcer. Sudden decreased use of the limb under a cast or increased lameness of the affected limb are signs of irritation under the cast. Another sign of such a problem is cast abuse through chewing, stomping, or rubbing. Swelling above the cast usually signifies a far more serious problem under the cast. Should any of these signs be noted, the cast should be changed or removed to alleviate the problem. Repairing a cast or making adjustments is not very often successful and is therefore not recommended.

Cast Removal

Removal of the cast with the horse under general anesthesia is usually uneventful. Removal of the cast while the horse is standing may be more complicated. In most cases, some degree of chemical or physical restraint is necessary to permit safe removal of the cast. If Gigli wires were incorporated into the cast, the ends can be freed up, connected to their handles, and with slow sawing motions the cast can be split in half (see Fig. 18-18, D). If cast cutters are used, the cast should be grooved medially and laterally along its entire length to ensure the correct location of the cut. Then, the proximal aspect of the cast is cut completely through, down to the foam or orthopedic felt. This allows assessment of the thickness of the cast and gives the person removing the cast an indication of how deep to cut. Using excessive force may result in perforation of the underlying skin. Once the proximal area of the cast is cut through, the rest of the cast should be cut by maintaining the blade at the same location until the cast is cut through completely before moving distally. Dragging the cast cutter parallel to the limb will promote skin lacerations. After the entire thickness of the cast has been cut through, the two portions of the cast tend to separate somewhat.

The cast covering the foot should be split carefully, because the density of the hoof is similar to that of the cast, and it is often difficult to differentiate between them, resulting in inadvertent penetration of the hoof wall by the saw blade. Although a standing horse may object to such treatment, there will be no reaction to this in the anesthetized animal.

Once the cast is split into two half shells, a cast spreader is applied to widen the gap and allow transection of the cast padding with scissors. The cast is removed and the limb washed thoroughly. If radiographs are made after cast removal, it is advisable not to wash the limb with soap containing iodine. After cast removal, the limb should be covered with a pressure bandage for some time to allow gradual relief of external pressure. Any sores that developed under the cast should be treated immediately using routine wound management.

In selected cases, a bivalve cast is applied to the limb. This can be carried out on the standing and sedated horse or with the horse under general anesthesia. In either case, the padding of the cast is made somewhat thicker and usually consists of a thin bandage, which can later be changed at regular intervals. The cast is subsequently applied using routine technique. It is advisable to let it set for about a day before splitting it into two half-shells. After the bandage is changed, the two shells are reapplied and maintained in apposition by tightly wrapping the two half-shells with nonadhesive tape.

Complications

Cast complications may develop from an overly tight application, resulting in dermal pressure necrosis (that will damage deeper structures if undetected) or in an overly loose application. If the cast is too loose, the limb can shift in the cast, which may result in the development of skin pressure in areas not anticipated. Cast loosening may result from a decrease in the limb swelling, from muscle atrophy, or from compacting of cast padding materials. Application of too-short a half-cast may result in severe tendon injury, because the limb may be partially flexed, causing the top end of the cast to apply a considerable amount of linear pressure on the unprotected tendons. In a properly applied cast, the tendons are protected by the proximal ends of the vestigial metacarpal or metatarsal bones. Wear on the bottom of the cast will also cause the limb to shift within the cast, resulting in serious dermal pressure necrosis.

REFERENCES

SURGICAL METHODS

Inhalation anesthesia is a versatile technique that facilitates many different types of surgical and diagnostic procedures in the equine patient, ranging from short to long, from elective to emergency, and from routine to complicated.

Halothane and methoxyflurane were introduced into clinical anesthetic practice in the early 1960s and their use became widespread in veterinary medicine. Methoxyflurane is no longer available because of the advent of novel inhalation anesthetics such as isoflurane (in the late 1970s) and more recently, sevoflurane and desflurane (in the 1990s). Halothane is also slowly disappearing from daily use in North America, although it continues to be widely used in Europe.

Novel drugs should provide significant advantages over previously used drugs if they are to replace them. Advantages of novel inhalation anesthetics should include less morbidity and mortality, better and more rapid control of anesthetic depth, less cardiorespiratory depression, and less biotransformation.

ANESTHETIC RISK

"A chance to cut is a chance to kill."

G. Mark Johnson

Complications arising from general anesthesia are common. Not all recognized complications reflect an immediate danger to the patient; however, identifying their significance and addressing them promptly may reduce their impact. Because most surgery is performed under general anesthesia, deaths during that time have been coined "anesthetic deaths." Some deaths can be considered as inevitable—for example, after rupture of major vessels. In addition, cardiac arrest can be a nonanesthetic event related to direct surgical complications, or it could be part of an anaphylactic reaction. Thus, not all causes of death are directly related to anesthesia. The most common causes of cardiac arrest associated with anesthesia include hypoxia because of ventilatory problems, drug overdose, and perioperative hypotension.

The anesthetic death rate in humans has decreased from 1 death per 2700 anesthesias in the 1950s, to 1 in 4761 in the 1970s, and to 1 in 10,000 in the 1980s. Anesthetic deaths have decreased over the years probably as a result of safer anesthetic drugs, better techniques, and more sophisticated monitoring and support equipment that allow early detection of problems and intervention. On the other hand, for these same reasons, it is now common to perform surgery or diagnostic procedures on critically ill patients, which contribute to the overall mortality rate despite recent anesthetic advances.

Equine studies have reported a death rate of 1 per 1250 anesthesias for elective procedures when only anesthetic causes are considered. Mortality increases to 1 in 158 cases when anesthetic and surgical causes, such as bleeding in the immediate postoperative period, fractured limbs during recovery, and shock, are included. If the entire hospitalization period from the time of anesthesia until the final outcome of the case is taken into account, then the overall death rate may be as high as 1 in 28.

Emergency cases had a higher overall death rate of 1 in 3.2 cases (1 in 2.8 for colic and 1 in 6.5 for noncolic cases) than elective cases when the entire hospitalization period is taken into account. Surgical and/or anesthetic deaths represented 1 in 23 cases in the colic group and 1 in 50 cases in the noncolic group if only the immediate postoperative period is considered. From these two studies, risk of death is 4.25 times more likely for emergency procedures not associated with colic than for similar procedures carried out electively. Emergency general anesthesia for colic carries an increased risk of death 9.86 times that of elective cases. These numbers are worrisome, but they include death by euthanasia, and that decision is influenced by many factors, including financial and prognosis for athletic future.

Morbidity and mortality studies are necessary to determine if one anesthetic drug or technique can positively influence outcome. However, these studies are difficult to design and execute because of the multiple factors involved. In an effort to identify drugs and techniques that may be linked to anesthetic death in horses, a confidential enquiry into perioperative equine fatalities (CEPEF) analyzed data from over 40,000 anesthetic records.

Findings from the CEPEF study identified an increased risk of death associated with techniques that involved an inhalation anesthetic only as part of the induction technique, a common practice in neonatal foals. Tachypnea and release of catecholamines have been suggested as possible causes that predispose to anesthetic overdose in foals, as well as increased overall requirement for the inhalation anesthetic because premedicant and induction agents are not used. Age was also linked to anesthetic death rate, which was highest in the very young, followed by the older horse, and lowest in young adults.
Maintenance of anesthesia with inhalation anesthetics carries a threefold higher risk of death than injectable anesthetics. Improved outcome with injectable anesthetics may reflect their use for shorter anesthetic procedures, as risk of death also increases with duration of anesthesia and surgery time, a situation in which injectable techniques are less likely to be used. In addition, intravenous anesthetics cause less cardiovascular depression than inhalation anesthetics. Most of the anesthetic deaths were related to cardiac arrest (33%), which explains the association between inhalation anesthetics and mortality. Of all anesthetic drugs and protocols used in over 35,400 cases, inhalation anesthetics were used as the maintenance agent in 87%, and injectables or no additional anesthetic were used for the remaining 13%. Despite the higher risk involved with inhalation anesthetics, the ease of administration with appropriate equipment and the ability to alter anesthetic depth makes them the most common method of maintaining anesthesia in equine patients at this time.

In a randomized prospective study that included elective and emergency cases from several equine clinics around the world, and with approximately 4100 horses receiving halothane and a similar number isoflurane, comparisons of mortality were similar; 1.7% versus 1.6%, respectively. The only difference between the two inhalants was demonstrated in horses 2 to 5 years of age, where the use of isoflurane reduced the death rate fivefold. The main causes of death in this study were cardiac arrest (32%) and fractures (23%). Isoflurane use was associated with less risk of cardiac-related mortality than halothane (30% versus 70% of cardiac deaths, respectively). Fractures may be related to poor perfusion to muscle groups secondary to cardiovascular depression and the subsequent myopathy that manifests in the recovery period. However, there were no significant differences between isoflurane and halothane in respect to myopathy. Duration of anesthesia (over 90 minutes) and lateral recumbency were the two factors that carried an increased risk of myopathy in this study. Despite the lack of evidence for advantages of isoflurane over halothane, it is generally agreed that isoflurane and novel inhalant anesthetics (sevoflurane and desflurane) depress myocardial function and cardiac output less than halothane and should be selected in more critical cases when perfusion and oxygenation may be impaired.

**ANESTHETIC DEPTH**

The novel inhalation anesthetics such as isoflurane, sevoflurane, and desflurane are less potent and less soluble than older agents such as halothane (Table 19-1). Potency is indicated by the minimum alveolar concentration (MAC), defined as the alveolar concentration of inhalation anesthetic that prevents movement in 50% of subjects in response to a noxious stimulus. Thus, the MAC of novel drugs is higher than that of the older drugs.

*These values are significantly lower in horses than for people.

The low lipid solubility (expressed as the blood/gas partition coefficient) of novel anesthetics is responsible for their lower potency because a higher concentration is required to achieve equilibrium between the two compartments (blood and alveoli) (see Table 19-1). The concentration of anesthetic in the alveoli is a reflection of the brain concentration for that particular drug. By controlling the concentration in the alveoli, with minimal impact from the lipid solubility of the drug in other tissues, changes in anesthetic plane can be achieved more readily and result in faster onset or disappearance of clinical effects.

In horses, a faster recovery is advantageous only if the animal has fully regained mental and motor function. The unique behavior of the horse compels it to assume a standing position early in the recovery period, and premature attempts to stand may result in a stormy recovery and major injuries. In the recovery period, horses attempt to move and change body position even when end-tidal anesthetic concentrations sufficient for clinical planes of anesthesia are still measurable. The administration of sedative drugs, including alpha-2 agonists, during this time has been advocated to prevent early movement attempts and improve the quality of recovery.

Duration of anesthesia also influences the quality of recovery. Isoflurane results in faster, but often less controlled, recoveries than halothane in horses anesthetized for periods of less than 2 hours. In horses anesthetized for periods of 3 hours or longer, the recoveries were better with isoflurane, as horses appeared more alert and less ataxic than after halothane. The solubility of halothane may account for more accumulation after a prolonged anesthetic delivery. In contrast, horses recovering from 1 hour of halothane anesthesia tended to have more ideal recoveries than horses recovering from 3 hours of halothane or isoflurane anesthesia. Sevoflurane results in more controlled recoveries than isoflurane, although no differences in times to standing were demonstrated between the two drugs. The better recoveries after sevoflurane may be the result of its lower solubility. In foals less than 3 months of age, no differences were detected in the induction or recovery times and quality scores between sevoflurane and isoflurane; however, these foals were assisted during recovery.

**CARDIORESPIRATORY EFFECTS**

In general, cardiovascular depression from inhalant anesthetics is dose dependent. Normally expressed as MAC...
multiples for the specific inhalant, the higher the MAC multiple delivered to the patient, the more pronounced was the cardiovascular depression. Using MAC multiples allows comparison of different inhalant anesthetics, based on the principle that there is equipotency between them at the same MAC level.

The cardiovascular effects of inhalant anesthetics can be divided into those that occur under mechanical ventilation and those under spontaneous ventilation. Dose-dependent decreases in cardiac output, stroke volume, and blood pressure are common with all inhalant anesthetics. However, these parameters are better maintained during spontaneous than during controlled ventilation because of the stimulatory effects of arterial CO$_{2}$, which is higher during spontaneous breathing.$^{9,19,20}$ In addition, changes in intrathoracic pressure that occur in ventilated horses have a negative effect on venous return that further depresses cardiac function.$^{10,20}$

Cardiac output, blood pressure, and systemic vascular resistance increased significantly from baseline in horses anesthetized with isoflurane during volume-controlled ventilation that allowed arterial CO$_{2}$ tensions to increase to moderate levels (PaCO$_{2}$ of 75 to 85 mm Hg) from normal values (35 to 45 mm Hg). In this same study, mild hypercapnia (55 to 65 mm Hg) caused only a minor decrease in cardiac output and an increase in vascular resistance.$^{19}$

In horses breathing spontaneously, cardiovascular variables were similar between isoflurane and halothane MAC multiples in one study,$^{14}$ and they were less depressed by isoflurane and sevoflurane than halothane in another.$^{11}$ Under controlled ventilation, isoflurane caused less depression of cardiac output and stroke volume than halothane, and similar changes in blood pressure, but vascular peripheral resistance was decreased with isoflurane more than with halothane.$^{11}$ Similar findings of better cardiovascular function with isoflurane compared with halothane have been described in horses anesthetized under hypoxic conditions (PaO$_{2}$ of 50 mm Hg) for 3 hours.$^{15}$ Changes in cardiac output, blood pressure, and peripheral vascular resistance are similar with isoflurane and sevoflurane at 1.5 MAC, which represents a moderate plane of surgical anesthesia.$^{11}$ Similarly, in foals anesthetized for approximately 1 hour, no differences between sevoflurane and isoflurane were detected in cardiovascular effects.$^{15}$ Desflurane causes cardiovascular changes similar to those caused by isoflurane and sevoflurane; it decreases vascular resistance and blood pressure, whereas cardiac output and heart rate remained unchanged at 1 MAC.$^{14}$

Halothane causes a decrease in blood pressure that is more related to a decrease in myocardial contractility and cardiac output than to a decrease in peripheral resistance. On the other hand, isoflurane, sevoflurane, and desflurane lower blood pressure as a result of decreased peripheral resistance and tend to cause less depression of cardiac output and contractility. Based on these findings, isoflurane, sevoflurane, and probably desflurane provide better tissue flow both in foals and adult horses and therefore may be safer, especially in the critically ill patient.

No major differences in heart rate are observed between isoflurane, sevoflurane, and halothane.$^{11}$ The arrhythmogenicity of halothane in response to doses of epinephrine is also higher than for isoflurane, sevoflurane, or desflurane.$^{21,23}$

Halothane-anesthetized horses breathe at a faster rate than horses on isoflurane. Respiratory rate also decreases progressively with increasing doses of isoflurane or sevoflurane but not with halothane.$^{30,31}$ Despite these differences, PaCO$_{2}$ tends to be similar with all inhalant anesthetics, indicating similar minute-ventilation with all of them, most probably as a result of an increased tidal volume in horses receiving isoflurane or sevoflurane, to compensate for the slower respiratory rate and a smaller tidal volume in horses receiving halothane.

In spontaneously breathing anesthetized horses, respiratory rate is decreased to a similar extent by isoflurane, sevoflurane, and desflurane and less by halothane.$^{11,14}$ The decrease in rate was accompanied by concomitant increases in PaCO$_{2}$.$^{8}$

**BIOTRANSFORMATION**

Respiration is responsible for eliminating most inhalation anesthetics. Liver metabolism is responsible for almost all degradation of inhalation anesthetics that remain in the body, although the lungs, kidneys, and other organs may contribute to overall elimination. Halothane is the only currently used inhalant anesthetic that undergoes extensive metabolism (up to 20%) by the liver. In comparison, isoflurane, sevoflurane, and desflurane are metabolized to a much lesser extent (0.2%, 3% to 5%, and 0.02%, respectively).$^{24}$

The effects of inhalant anesthetics on hepatic blood flow and metabolism should be minimal so that hepatic function is sustained and toxicity problems are avoided. In animal studies that have included dogs, rats, and pigs, the novel inhalant anesthetics including isoflurane, sevoflurane, and desflurane preserve hepatic metabolism and splanchnic blood flow better than halothane.$^{25-28}$ Similarly, in humans, all three of the novel anesthetics are preferred over halothane in patients with liver disease.$^{29}$

Research horses anesthetized for up to 5 hours with only halothane and maintained at 1 to 2 MAC during this time exhibited a significant increase from baseline in aspartate aminotransferase, lactate dehydrogenase, creatinine phosphokinase, and total bilirubin for up to 4 days after anesthesia.$^{30}$ Similar changes are observed, although significantly less pronounced, when anesthesia time with halothane is less than 2 hours in clinical cases.$^{31}$ In contrast, horses exposed to isoflurane for 5 hours at 1 to 2 MAC did not exhibit significant changes in their serum chemistry values.$^{32}$ In a subsequent study, the same authors demonstrated that increasing anesthetic time with halothane beyond 5 hours increases the magnitude and duration of these changes, suggesting liver dysfunction.$^{32}$ Hepatic dysfunction in horses has been associated with halothane anesthesia combined with hypoxemia, but not with isoflurane and hypoxemia.$^{15}$

Halothane has been implicated in cases of hepatic dysfunction in other species. Hepatic hypoxia with halothane is reported to be a major cause of such changes because greater reductions in hepatic blood flow occur with halothane than with other inhalation anesthetics. In addition, the increased biotransformation (20%) in the presence of reduced blood flow and oxygenation will promote a reduction of metabolism. As mentioned before, only halothane undergoes this
type of metabolism. However, a reduction of metabolism is not always linked directly to hepatotoxicity, as hepatic damage also occurs with other anesthetics.7

GENERAL RECOMMENDATIONS

The transition from induction of anesthesia with injectable agents to inhalation anesthesia, and then to emergence from inhalation anesthesia, should be smooth. The use of injectable drugs with sedative or anesthetic properties is advised, especially in the neonate, as shown by mortality studies.

High oxygen flows should be used in the first 10 to 15 minutes of anesthesia to carry the inhalation anesthetic into the circuit and overcome the dilution effects of the anesthetic equipment (canister, reservoir bag, and breathing circuit), the horse’s tidal volume and concentration gradients. In the adult horse, oxygen flows of 20 mL/kg per minute are normally used, inclusive, the first part of anesthesia and then lowered to 10 mL/kg per minute for the remainder of the anesthetic period. In foals, flows of 40 to 60 mL/kg per minute are adequate, and this has less impact on cost and allows the use of small animal anesthetic machines.

Carbon dioxide absorbers should be monitored and changed regularly, usually after 5 to 7 hours of use at the oxygen flow rates just described. This also prevents accumulation of carbon monoxide, which may occur especially with desflurane, isoflurane, and halothane when low oxygen flows are used and soda lime is the choice of carbon dioxide absorbent. Production of compound A from sevoflurane in the presence of barium lime, and to a lesser degree with soda lime, can occur when low oxygen flows are used. This compound is reported to be nephrotoxic in rats,8 and although similar data are not available in horses, caution is advised.

In conclusion, novel inhalation anesthetics with lower blood/gas partition coefficients have been introduced over the last 40 years. The advantages of these drugs are less biotransformation, less cardiovascular depression, and more rapid changes in anesthetic depth. Isoflurane, sevoflurane, and desflurane are drugs with similar anesthetic effects in the horse and the choice of agent depends on personal preference, available vaporizers, and financial considerations. Whether the novel agents will result in lower fatality rates remains to be seen.

MODERN INJECTION ANESTHESIA

CHAPTER 20

Modern Injection Anesthesia for Horses
Regula Bettschart-Wolfensberger

The use of inhalational anesthesia is generally limited to larger clinics because of equipment costs, the requirement for an oxygen source, and the need for a scavenging system for waste gases. There is also strong evidence that inhalant techniques are associated with a higher mortality rate in horses (see Chapter 19). Therefore, the use of safe intravenous anesthesia techniques in practice is both desirable and advantageous. The most important features of intravenous protocols are a smooth, excitement-free induction phase with a slow lowering of the body into sternal and lateral recumbency, minimal cardiopulmonary depression, and a calm recovery with a single attempt to stand and minimal ataxia. Other factors include good muscle relaxation, analgesia, as well as the possibility to assess depth and duration of anesthesia in a quick and predictable manner.

Intravenous anesthetic combinations are presently used for anesthesia induction and for short (up to 30 minutes), minor surgical procedures. Longer surgeries are performed with intravenous anesthesia induction followed by inhalation, or less commonly by total intravenous anesthesia (TIVA). Features of short-duration injection anesthesia are discussed separately from long-duration (anesthetic duration over 30 minutes) TIVA. Anesthetics discussed in this chapter include ketamine and propofol and useful combinations of these two drugs. Older agents such as barbiturates, chloral hydrate, and drugs suitable for the anesthesia of wild Equidae, such as Immobilon (etorphine-acepromazine), will not be discussed.

SHORT-DURATION INJECTION ANESTHESIA

For anesthesia induction, ketamine, tiletamine/zolazepam, or propofol can be used. Adult horses must be adequately sedated before anesthesia induction with a calculated dosage of the selected drug. Only in very young foals and in recumbent, severely compromised horses can anesthesia be induced with administration of an anesthetic to effect. For compromised horses, a mixture of equal volumes of diazepam (5 mg/mL) and ketamine (100 mg/mL) is a safe method for anesthesia induction and usually requires 1 mL/25 kg of the mixture (0.1 mg/kg diazepam + 2 mg/kg ketamine). This protocol avoids the cardiovascular-compromising side effects of α2-agonists. In foals, the administration of propofol to effect is an alternative (see Chapter 21).

Ketamine

Ketamine is the most widely used drug for anesthesia induction in horses. It provides good, mainly somatic analgesia without inducing hypnosis. However, it is not suitable as a sole agent, as it may cause seizure-like activity and muscle rigidity. Appropriate sedation with α2-agonists or acepromazine prior to induction is very important.144 The additional use of drugs such as guaifenesin or benzodiazepines (diazepam or midazolam) will further improve muscle relaxation.15,20 Guaifenesin is a safe drug with minimal side effects at clinical dosages. It should be used as a 5% (50 mg/mL) solution, because higher concentrations are associated with significant irritation of the veins21 and intravenous hemolysis.

Guaifenesin is administered to the sedated horse to effect (preferably under pressure, as effective dosages are large—often 50 mg/kg, or 500 mL for a 500-kg horse). When the horse begins to buckle at the knees, the induction drug, most commonly ketamine (2 mg/kg), should be given.
CHAPTER 20

Modern Injection Anesthesia for Horses
Regula Bettschart-Wolfensberger

The use of inhalational anesthesia is generally limited to larger clinics because of equipment costs, the requirement for an oxygen source, and the need for a scavenging system for waste gases. There is also strong evidence that inhalant techniques are associated with a higher mortality rate in horses (see Chapter 19). Therefore, the use of safe intravenous anesthesia techniques in practice is both desirable and advantageous. The most important features of intravenous protocols are a smooth, excitement-free induction phase with a slow lowering of the body into sternal and lateral recumbency, minimal cardiopulmonary depression, and a calm recovery with a single attempt to stand and minimal ataxia. Other factors include good muscle relaxation and analgesia, as well as the possibility to assess depth of anesthesia and modify depth and duration of anesthesia in a quick and predictable manner.

Injectable anesthetic combinations are presently used for anesthesia induction and for short (up to 30 minutes), minor surgical procedures. Longer surgeries are performed with intravenous anesthesia induction followed by inhalation, or less commonly by total intravenous anesthesia (TIVA). Features of short-duration injection anesthesia are discussed separately from long-duration (anesthetic duration over 30 minutes) TIVA. Anesthetics discussed in this chapter include ketamine and propofol and useful combinations of these two drugs. Older agents such as barbiturates, chloral hydrate, and drugs suitable for the anesthesia of wild Equidae, such as Immobilon (etorphine-acepromazine), will not be discussed.

SHORT-DURATION INJECTION ANESTHESIA

For anesthesia induction, ketamine, tiletamine/zolazepam, or propofol can be used. Adult horses must be adequately sedated before anesthesia induction with a calculated dosage of the selected drug. Only in very young foals and in recumbent, severely compromised horses can anesthesia be induced with administration of an anesthetic to effect. For compromised horses, a mixture of equal volumes of diazepam (5 mg/mL) and ketamine (100 mg/mL) is a safe method for anesthesia induction and usually requires 1 mL/25 kg of the mixture (0.1 mg/kg diazepam + 2 mg/kg ketamine). This protocol avoids the cardiovascular-compromising side effects of α2-agonists. In foals, the administration of propofol to effect is an alternative (see Chapter 21).

Ketamine

Ketamine is the most widely used drug for anesthesia induction in horses. It provides good, mainly somatic analgesia without inducing hypnosis. However, it is not suitable as a sole agent, as it may cause seizure-like activity and muscle rigidity. Appropriate sedation with α2-agonists or acepromazine prior to induction is very important. The additional use of drugs such as guaifenesin or benzodiazepines (diazepam or midazolam) will further improve muscle relaxation. Guaifenesin is a safe drug with minimal side effects at clinical dosages. It should be used as a 5% (50 mg/mL) solution, because higher concentrations are associated with significant irritation of the veins and intravenous hemolysis.

Guaifenesin is administered to the sedated horse to effect (preferably under pressure, as effective dosages are large—often 50 mg/kg, or 500 mL for a 500-kg horse). When the horse begins to buckle at the knees, the induction drug, most commonly ketamine (2 mg/kg), should be given.

Benzodiazepines can be used instead of guaifenesin and can be given mixed with ketamine without causing irritation of the vein. Depending on the dosage used, these drugs may increase the respiratory depression caused by ketamine. To reduce the risk of apnea in the field when respiratory support is not available, low dosages of benzodiazepines (0.02 mg/kg diazepam or midazolam IV) are advocated. For anesthesia induction followed by inhalation anesthesia, higher dosages (up to 0.2 mg/kg IV) can be used and will facilitate intubation. Mechanical ventilation will counteract respiratory depression. To guarantee adequate muscle relaxation in the field where low dosages of benzodiazepines should be used, very deep sedation with relatively high dosages of α₂-adrenoceptor agonists is recommended.

Ketamine is a safe anesthetic for horses. Properly sedated, undisturbed horses will slowly sink into sternal and then lateral recumbency. Recovery at the end of anesthesia is usually quick and coordinated. Respiratory depression is minimal. Ketamine’s sympathomimetic action is ideal to counteract the bradycardia and hypotensive effects of the drugs used as sedatives. For example, xylazine has been shown to have only minimal influence on cardiovascular function in combination with ketamine in the horse. The judgment of depth of anesthesia can be difficult until one is familiar with these techniques, because the eyes remain open and the reflexes are only minimally depressed. Movements as a result of awakening may occur very suddenly and may be of a strong nature. In healthy horses, I prefer the administration of ketamine according to a fixed time scheme rather than to effect (Table 20-1).

**Tiletamine**

Tiletamine is a drug similar to ketamine, and both are classified as dissociative agents. It is commercially available as a powder in a fixed (1:1) combination with zolazepam, a benzodiazepine, and it is reconstituted with sterile water immediately before use. It has been used in horses and other Equidae at dosage ranges of 1.1 to 1.65 mg/kg IV after sedation with α₂-adrenoceptor agonists. Depending on the dosage selected, the recumbency time was considerably longer than with ketamine combinations, and respiratory depression was more pronounced. Ataxia during recovery was more accentuated than with ketamine, with horses making several attempts to stand up. This feature makes this combination less desirable than xylazine-ketamine.

**Propofol**

Propofol is a short-acting anesthetic that provides very good hypnosis and muscle relaxation but poor analgesia. It is not suitable as a sole agent in adult horses because anesthesia inductions are unpredictable, and the large volumes required make it impractical and prohibitively expensive. Propofol has been used mainly after sedation with α₂-adrenoceptor agonists under experimental conditions. Only a few investigations have looked at propofol in clinical patients. Some authors were happy with propofol as an induction agent. Others reported that the quality of anesthesia induction in individual horses was “not ideal” or “unacceptable.” It was questioned whether slow administration of propofol would smooth anesthesia induction, but other factors, such as respiratory depression and lack of inherent analgesia in addition to cost, have prevented widespread use of propofol for anesthesia induction and maintenance of anesthesia during short surgical procedures.

In the neonatal foal, the use of propofol, administered to effect, for anesthesia induction (approximate dosage, 2 mg/kg IV) is, however, a good alternative to ketamine, as the duration of action of propofol is short and not dependent on time.

on liver function. Relaxation is better and thus endotracheal intubation easier than with ketamine. Propofol is contraindicated in hypotensive foals, because it will further compromise these patients (see Chapter 21).

**TOTAL INTRAVENOUS ANESTHESIA OF GREATER THAN 30 MINUTES’ DURATION**

Drugs and dosages suggested for maintenance of anesthesia with TIVA in horses are summarized in Table 20-2.

In modern equine practice, TIVA of longer duration is commonly maintained with constant infusions of the so-called triple drip (guaifenesin + α₂-agonist + ketamine), ketamine-climazolam, or propofol in combination with various drugs.

Ketamine combinations can be safely used for up to 1.5 hours to perform minor surgeries in the field. A recumbent horse breathing air will, however, become hypoxic. To prevent complications associated with hypoxia during field procedures of 30 minutes or longer, inspired air should be supplemented with oxygen (15 L/min, via a nasal or endotracheal tube). If the duration of anesthesia exceeds 2 hours, ketamine should not be used, because it produces active metabolites that are eliminated very slowly and thus negatively influence the recovery period.

**Ketamine-Guaifenesin-α₂-Adrenoceptor Agonist**

The triple-drip drug combinations are the most widely used for TIVA. The most commonly used combination is ketamine, guaifenesin, and xylazine. Cardiovascular and respiratory depressions are minimal, and these combinations have been successfully used to perform major surgical procedures as well as to prolong field anesthesia in a relatively controlled manner. The use of this combination should be restricted to procedures of up to 2 hours’ duration, not only because of the cumulative effects of metabolites of ketamine but also because large doses of guaifenesin may result in severe ataxia during recovery. Anesthetic induction performed prior to triple-drip anesthesia should not include guaifenesin, so that the total amount of guaifenesin given to the individual is as low as possible. A suitable induction technique is xylazine followed by ketamine. Because guaifenesin is a centrally acting muscle relaxant, the lack of movements during anesthesia is not a guarantee of adequate analgesia. During painful procedures, analgesia should be provided with local anesthesia or the inclusion of opioids such as butorphanol or morphine.

**Ketamine-Climazolam**

The infusion of climazolam (a long acting benzodiazepine) together with ketamine causes less cardiovascular depression than triple-drip techniques. Because climazolam causes severe ataxia, its action has to be reversed with sarmazenil for recovery. Analgesia is sufficient to perform superficial surgeries causing somatic pain. To provide sufficient analgesia for visceral procedures, local anesthesia or additional analgesia (opioids, α₂-agonists) must be administered.

**Propofol**

In contrast to ketamine, propofol is an ideal anesthetic for prolonged TIVA. It possesses a short context-sensitive half-life, permitting rapid recovery. It has been used in combination with different α₂-adrenoceptor agonists, guaifenesin, ketamine, and opioids. In combination with medetomidine, anesthesia was maintained for up to 4 hours, and major surgeries were successfully performed. Although recovery was uneventful and relatively quick in all reports, problems, mainly of a respiratory nature (apnea and severe respiratory acidosis), and the relatively high cost of propofol have prevented its widespread use in clinical practice. Also, it offers no major advantages over commonly used inhalation anesthetic protocols—an additional reason for its limited use.

Foals undergo a rapid physiologic transition during the first year of life. Many changes involving the respiratory, cardiovascular, central nervous, and renal systems are unique to foals, and they have a major impact on their anesthetic management. Foals require sedation or general anesthesia for a variety of reasons, but the most common procedures are orthopedic and urogenital. The overall perioperative mortality rate for equine patients under 1 year of age is 1.9%, which is higher than the rate reported for the general horse population.1,2 Foals between birth and 4 weeks of age pose the greatest risk associated with anesthesia, and within this group abdominal surgery has the highest mortality rate. Data show that the choice of anesthetic technique has a significant impact on outcome.

Despite the risks, the demand for anesthesia in critically ill foals sent to referral centers is greater than ever. Newer surgical and imaging techniques that require general anesthesia, such as laparoscopy3 and magnetic resonance imaging (MRI),4 are becoming popular. Importantly, pain management is an integral component of perioperative care, and techniques that are appropriate for foals must be included in the anesthetic plan.

### RISKS ASSOCIATED WITH ANESTHESIA IN FOALS

Although outcomes have been reported for surgical treatment of colic5 and uroperitoneum6 in foals, it has been difficult to differentiate between mortality associated with anesthesia itself and the surgical procedure. The Confidential Enquiry into Perioperative Equine Fatalities (CEPEF) is an observational multi-institutional prospective study of recovery outcome at 7 days postoperatively, which was initiated by Johnston and others in 1991 to provide evidence-based data on risk factors associated with equine anesthesia.7 This study is the basis for the following discussion on anesthetic risk in foals.

The most common procedures performed in foals include orthopedic surgery (correction of angular limb deformities and joint flushes) and urogenital surgery (Table 21-1). The greatest risk associated with anesthesia and surgery occurs in foals between birth and 4 weeks of age (Table 21-2), and abdominal surgery is the procedure that carries the highest mortality rate (Table 21-3).

ENT, ear, nose, or throat surgery.

### PHYSIOLOGY OF NORMAL FOALS

The anesthetist must be aware of the normal physiologic values in healthy foals to avoid misinterpretation of data.7–10 For example, murmurs may be “normal” and arterial oxygen values low in the first week of life.

#### Cardiovascular System

Heart rates are approximately 100 beats per minute during the first month of life, decreasing to an average of 77 at 2 months and 60 at 3 months of age7,10 (Table 21-5). These changes most likely reflect a transition from sympathetic dominance to increased vagal influence as the cardiovascular system matures.

Echocardiographic evidence indicates that left ventricular function (as measured by the shortening fraction) is similar in foals and adults,10 but cardiac output is primarily rate dependent. If cardiac indices are adjusted for metabolic size, foals have a cardiac index (mL/min per kilogram) at least...
twice that of adults, yet their stroke volume is lower (see Table 21-5). Therefore, any decrease in a foal's heart rate has a significant impact on cardiac output.

Mean arterial blood pressure (MAP) values vary with the measurement technique employed. If indirect techniques such as Doppler ultrasound or electronic sphygmomanometry are used, the MAP may be as low as 50 mm Hg in normal 1-day-old foals, rising to 60 to 70 mm Hg at 2 to 3 weeks of age. More recently, indirect oscillometric techniques have been validated against direct arterial blood pressure measurement, and true blood pressure readings are higher than those reported from Doppler studies. MAP dictates organ perfusion; therefore, this is the most valuable blood pressure variable to obtain. In conscious 30- to 46-hour-old foals, direct MAP ranged from 59 to 113 mm Hg and from 69 to 111 mm Hg using oscillometric techniques.

### Respiratory System
Respiratory rate is high at birth, and it declines over the first 6 months of life. At 1 week of age, the respiratory rate (43 ± 8 breaths/min) is four times that of adult horses.

Minute ventilation also declines over this age range, with the high values early in life being necessary to meet the high metabolic rate of foals. Oxygen consumption in 1- to 7-day-old foals is 6 to 8 mL/kg per minute, which is two to three times that of adults, and this must be taken into account when low-flow anesthetic techniques are used. Tidal volume in foals is similar to that in adults, as are values for arterial partial pressure of carbon dioxide. Some of these variables are shown in Table 21-6.

Newborn foals are hypoxic. At 1 hour of age, values are 60.9 ± 2.7 (mean ± standard error of the mean) mm Hg and gradually increase to 86.9 ± 2.2 mm Hg by day 7, which is still below adult values of 104 ± 5 mm Hg. Body position influences arterial oxygenation, with values up to 14 mm Hg lower in foals that are laterally recumbent than in foals in the upright position. The anesthetist should also be aware of the age-related responses to oxygen administration. Although the rise in arterial oxygen pressure (PaO₂) with oxygen therapy in normal foals is significant, the response is much less in the first 2 days of life compared with day 7 and is not influenced by duration of oxygen therapy (2 minutes versus 20 minutes) or method of administration (face mask versus nasal insufflation). The changes in response to oxygen may be a result of dural closure or differences in ventilation and perfusion. Premature foals failed to show a response to oxygen therapy, and this should be borne in mind when emergency anesthesia is performed in these patients.

Renal Function
Renal function is an important determinant of the excretion of many drugs. Studies show that although foal kidneys may be structurally immature, they are functionally mature. The glomerular filtration rate and effective renal plasma flow from 1 to 10 days of age are not significantly different from those of adults. Blood urea nitrogen values of less than 2 mmol/L are normal up to 3 months of age, whereas the mean adult value is 3.5 mmol/L. Rapid incorporation of amino acids into proteins is thought to be the cause of the low value in foals. Urine production in 4-day-old foals was 148 ± 20 mL/kg per day and had a low specific gravity (less than 1.008). Iohexol clearance may offer a clinically useful method for assessing renal function in neonatal foals. In normal 1- to 10-day-old foals, the pharmacokinetics of amikacin, a renally excreted antibiotic, suggest maturation of kidney function during this time. Hypoxemia and azotemia can markedly alter excretion of amikacin, and the dosage and dosing interval of renally excreted drugs may require adjustment in compromised foals.

Central Nervous System
Changes in drug disposition in growing foals may be explained by alterations in body composition, hepatic metabolism, and renal excretion. An additional factor to consider, especially in regard to anesthetic agents, whose site of action is the central nervous system (CNS), is the permeability of the blood-brain barrier, which separates cerebral spinal fluid (CSF) and nervous tissue from the intravascular compartment. Age-related changes in permeability have been reported in some species, but much less is known about the foal. The buffering ability of the CSF is also important to consider, as changes in CNS pH may directly affect brain function and may also alter drug dissociation and action.

Geiser and colleagues studied the CSF buffering capacity of foals less than 12 days of age by measuring the pH and PaCO₂ of arterial and venous blood and the CSF during normocapnia and hypercapnia. As in other neonates, the CSF of foals was more acidic than blood during normocapnia (PaCO₂ 35 to 40 mm Hg). Hypercapnia (PaCO₂ greater than 45 mm Hg) produced a rapid increase in CSF PaCO₂ and a drop in pH. In contrast with blood, the buffering capacity of the CSF was poor and can be explained by the lack of protein, a major buffering system in blood, and the low permeability of the blood–CSF interface to bicarbonate ions compared with highly soluble CO₂. Acute increases in PaCO₂ that may occur in sick, sedated, or anesthetized neonatal foals may have far-reaching effects not only because of their poor CSF buffering capacity but also as a result of vasodilation of cerebral vessels, which results in increased cerebral blood flow and intracranial pressure.

Clinical Chemistry

Bauer and coworkers monitored serum chemistry values in several equine breeds during the first year of life and reported significant changes for alkaline phosphatase, aspartate transaminase, urea nitrogen, and total, direct, and indirect bilirubin, but not for electrolytes or glucose, emphasizing the need to consult age-specific reference values when interpreting this information in a clinical situation.

Mean serum glucose values ranged from 8.0 to 9.3 mmol/L during the first 3 months, with foals less than 12 hours of age having values of 8.0 ± 1.6 mmol/L. Smyth and colleagues reported that 1-day-old foals that had been fasted for 2 hours had serum glucose values of 6.0 ± 0.7 mmol/L. Full-term foals were able to maintain plasma glucose values for 2 hours after birth without suckling, but premature foals had mean values of only 2.31 mmol/L.

Blood lactate is a useful indicator of tissue perfusion, but reference values may vary with age and source of the sample. In Thoroughbred foals aged 1 to 6 months, jugular blood lactate values ranged from 0.9 to 1.65 mmol/L, whereas arterial blood lactate values in 2-day-old foals were 2.17 ± 0.49 mmol/L.

Hematology

Hematologic values change during a foal’s first 12 months. Hemoglobin and packed cell volume (PCV) fell during the first 2 weeks of life and then remained in the low normal range reported for adults, with no differences noted between Thoroughbred and Quarter Horse foals. PCV was 0.43 ± 0.03, 0.40 ± 0.03, 0.38 ± 0.03 L/L at birth, 1 and 3 days respectively and progressively fell to 0.34 ± 0.04 L/L at 1 month of age. Hemoglobin and PCV values lower than those reported for healthy foals may result in decreased oxygen delivery to tissues. Total plasma proteins values were 60 ± 8 g/L at day 1 and did not vary more than 10% during the first year.

PHARMACOKINETICS

The disposition of many drugs in foals is different from that in adults, and appropriate changes in both dosage and dose interval may be needed to avoid subtherapeutic or toxic concentrations. Pharmacokinetics may be influenced by both body composition and organ maturation, especially hepatic and renal function. For several drugs, marked pharmacokinetic differences have been noted between newborns, 1-week-old foals, 1-month-old foals, and foals older than 1 month. As a percentage of their body weight, foals have greater total body water, blood plasma, and extracellular fluid (ECF) volumes than adults (see Chapter 3). In foals up to 1 month of age, the ECF accounts for 35% to 40% of body weight, compared with 25% in adult horses, and this may influence the uptake and distribution of anesthetic drugs.

Hepatic Metabolism

The liver is the main site of drug metabolism, and it is important to have data on age-related hepatic function so that the anesthetist can make appropriate drug choices. The pharmacokinetics of chloramphenicol during the first week of life suggest that glucuronide synthesis matures rapidly in normal foals, but the longer half-life in one premature foal indicates that their livers are less mature. Elevated bilirubin values in the first week of life may be a result of low glucuronyl transferase activity in foals.

SEDATION

Foals require sedation for a variety of reasons, including radiography, bandage and cast changes, intravenous catheter placement, intensive care procedures, and arthrocentesis, and they should be sedated prior to general anesthesia. Information on the effects of the commonly used sedatives (xylazine, detomidine, diazepam, acepromazine) on foals is available.

There are no significant differences in the cardiopulmonary responses to high dosages (1.1 mg/kg IV) of the alpha2-agonist xylazine in healthy 10- and 28-day-old foals. Unlike adults given a similar dosage, most foals become recumbent. Foals’ heart rates fell by about 20% to 30% without the second-degree atrioventricular block that is typically seen in adults. A biphasic (initial increase followed by a decrease) change in blood pressure, similar to that in adult horses, occurred, but the MAP did not fall below 60 mm Hg. Respiratory rhythm is markedly disrupted after xylazine administration in foals. Frequent upper airway noise indicative of respiratory obstruction lasted for 20 minutes, after which time respiration became slow and regular. The noise is thought to result from upper airway collapse secondary to muscle weakness. Despite this response, healthy foals showed no changes in PaO₂ or PaCO₂. Foals with respiratory disease, including those with preexisting upper airway obstructions such as guttural pouch tympany or strangles, may not compensate for these respiratory insults and should not be given xylazine. Alternatively, it can be given after establishing an airway by nasotracheal intubation. Lower dosages (0.2 to 0.3 mg/kg IV) provide adequate sedation in a clinical setting and are associated with fewer cardiovascular changes.

Rectal temperature fell significantly after xylazine administration in foals and remained low for more than 2 hours, by which time the sedative effects had worn off. Body temperature should be monitored in all foals given xylazine, and extremes of environmental temperature are best avoided. Unlike in adult horses, xylazine did not produce hypoinsulinemia and hyperglycemia in 10- and 28-day-old foals, suggesting differences in pancreatic response to α2-adrenergic agonists in neonates. Increased urination occurs after xylazine administration, and this should be considered when it is used to sedate hypovolemic foals.

Detomidine has been studied in foals between 2 weeks and 3 months of age. Increasing the IV dosage from 10 to 40 µg/kg did not provide a greater degree of sedation, but it did prolong the duration of action: sedation lasted 28 ± 4 minutes after 10 µg/kg, and 73 ± 7 minutes after 40 µg/kg. Analgesia as assessed by skin prick was noted only at the 40-µg/kg dosage, but this was inconsistent and present in less than 50% of foals. As in xylazine-treated foals, respiratory stridor and increased urine production were observed. Unlike in foals given xylazine, recumbency did not occur even after high dosages of detomidine. This agent is less...
Desirable than xylazine for sedation and analgesia of young foals, as even low dosages (10 µg/kg) are associated with a 60% incidence of arrhythmias. 41

Diazepam is widely used in foals as a tranquilizer, muscle relaxant, and anticonvulsant. The pharmacokinetics of diazepam at a commonly used clinical dosage (0.25 mg/kg IV) have been studied in foals at 4, 21, 42, and 84 days of age. 42 Several pharmacokinetic variables were different when the 4-day-old foals were compared with foals of the other ages; the most clinically significant difference was the lower clearance in the 4-day-old age group, because this determines whether or not diazepam could accumulate if repeated doses or constant-rate infusions are used. In foals 21 days and older, pharmacokinetic data were similar to those reported for adult horses. 42-43 Compared with the values seen in other adult species, the free fraction of diazepam was much higher, and this could result in a greater clinical effect. 42 Lower binding ability of fetal albumin or competition for binding sites by elevated bilirubin levels in foals may explain this relatively high free fraction. The active metabolite desmethyldiazepam was measurable in all foals between 4 and 84 days of age but was not detected in adult horses after administration of diazepam. 43 These data suggest a difference between foals and adults in hepatic biotransformation and elimination of drugs. The cardiopulmonary effects of diazepam have not been reported in foals, but dosages of up to 0.4 mg/kg produced no changes in cardiac output, blood pressure, or blood gas values in adult horses. 43

Clinical effects of diazepam in foals are not widely documented. One study comparing xylazine to diazepam plus butorphanol as a premedicant for foals undergoing perioveal stripping concluded that xylazine provided better muscle relaxation. 44 When diazepam (0.1 to 0.2 mg/kg IV) is administered to foals less than 2 months of age, the usual response is profound sedation, muscle relaxation, and recumbency, whereas in older foals (2 to 4 months old), sedation and muscle relaxation are less pronounced and not always accompanied by recumbency (in my personal experience). These observations correlate with the research studies described earlier. These age-related responses may occur because of differences in permeability of the blood-brain barrier in younger foals.

Acepromazine can be used in foals, and commonly used dosages are 0.03 to 0.05 mg/kg (IM or IV). In adult horses, acepromazine decreases the mortality rate associated with general anesthesia, which may be a reflection of its antiarrhythmic properties. Hypotension secondary to vasodilation is not observed unless foals are hypovolemic. Vasodilation and sedation may enhance heat loss, but there are no reported studies confirming this.

THE PREANESTHETIC PERIOD

The preoperative workup varies depending on the physical status of the foal and the intended surgical procedure. Blood work and physical examination results must be correlated with the distinct age-related changes described earlier. Electrolytes should be measured in foals with uroperitoneum; in one study, 48% of foals had abnormalities, which included hyponatremia, hypochloremia, and hyperkalemia accompanied by a metabolic acidosis. 43-45 Hyperkalemia may be associated with cardiac arrhythmias, which increases the anesthetic risk and must be corrected before surgery. Serum potassium can be decreased by draining the abdomen, by administering intravenous fluids (0.9% NaCl or 5% dextrose), and by correcting the metabolic acidosis with sodium bicarbonate. Insulin is only rarely required.

Although the focus of attention is the foal, the mare must not be forgotten. Allowing the dam to be present at induction of anesthesia is extremely valuable, because this ensures a calm foal. Sucking prior to anesthesia ensures adequate blood glucose levels, and regurgitation or vomiting is not a problem. After the foal has lost consciousness, the mare can be housed nearby but must be sedated, as most mares become agitated when separated from their foals. Xylazine (0.3 to 0.5 mg/kg IV) or detomidine (0.01 mg/kg IV) produces rapid and profound sedation in mares that can be extended by the addition of acepromazine (0.04 mg/kg IM).

GENERAL ANESTHESIA

Injectable Agents

Matthews and coworkers reported their experiences with propofol in healthy foals. 46 Their protocol was 0.5 mg/kg of xylazine IV followed 5 minutes later by a bolus of propofol (2 to 3 mg/kg) given over 45 to 60 seconds. As in other species, propofol must be given slowly to prevent apnea. Immediately after induction, foals were intubated, they were given 100% oxygen, and an infusion of propofol was started (approximately 0.3 mg/kg per minute). After infusions of up to 2 hours, foals had smooth and rapid recoveries. Cardiopulmonary variables were generally well maintained even when foals were placed in dorsal recumbency. A mild respiratory acidosis (PaCO2 of 60 mm Hg or less) was documented but considered clinically acceptable in healthy foals. It must be emphasized that these foals were all given oxygen supplementation, as hemoglobin saturation declines significantly if foals are allowed to breathe room air during propofol anesthesia (my personal experience).

Foals may react to surgical stimuli when anesthesia is maintained with propofol alone. Therefore, this technique is more suited for short, nonpainful procedures such as cast changes and radiography, when a rapid smooth recovery is desirable. Alternatively, propofol anesthesia could be combined with a local anesthetic in some situations, or sedatives, analgesics, or dissociative agents such as xylazine, butorphanol, or ketamine (respectively) could be added to the protocol. Propofol used alone without premedication provides approximately 5 minutes of general anesthesia. In dogs, propofol is an appropriate agent for patients with neurologic disease. 47-48 In foals, a single bolus should be adequate for collection of CSF samples. For MRI studies in foals suffering from neurologic disorders, propofol could be administered as a continuous infusion, and in these patients, PaCO2 should be closely monitored and hypercapnia avoided.

The pharmacokinetics of ketamine have not been described for the foal, but in adult horses recovery after a bolus results from redistribution. 49 Ketamine at a dosage of 2.2 mg/kg IV is recommended for foals and is usually given after premedication with xylazine or diazepam, or after administration of the centrally acting muscle relaxant guaifenesin. 50
**Total Intravenous Anesthesia**

TIVA is associated with a lower mortality rate in both adults and foals. The so-called triple drip is widely used in foals, but oxygen supplementation is required to prevent hypoxemia. Dunlop recommends making a triple-drip mixture using a 1-L bag of 5% guaifenesin and adding 250 mg of xylazine and 1000 mg of ketamine. Induction can be achieved with 1 to 2 mL/kg of this mixture. Anesthesia is maintained using a rate of 2 to 3 mL/kg per hour, with the infusion rate adjusted on the basis of the clinical signs of depth of anesthesia. TIVA techniques are discussed fully in Chapter 20.

**Inhalant Agents**

The CEPEF data strongly suggest using TIVA techniques, or to induce the patient with injectable agents followed by maintenance with inhalant agents rather than relying totally on inhalant agents. For the foreseeable future, inhalant agents will continue to be used in foals, so the advantages and disadvantages of each should be well understood.

The time from induction to lateral recumbency was the same for halothane and isoflurane (approximately 4½ minutes) when administered by mask to unmedicated foals up to 2 months of age, and induction was smooth in both groups. After 80 to 90 minutes of anesthesia, time to sternal recumbency was significantly faster in the isoflurane group (8.03 ± 0.93 minutes) than in the halothane group (13.6 ± 1.5 minutes); however, time to suckling was not different. Both agents were associated with a similar increase in PaCO₂ values despite the lower respiratory rate in isoflurane-anesthetized foals. In adult horses, there is no difference in overall mortality between halothane and isoflurane, but such data are not yet available for neonatal foals.

Sevoflurane is the most recent inhalant agent to be introduced to the veterinary market. In adult horses, its cardiopulmonary effects are similar to those of isoflurane, but recovery is more rapid because of its low solubility. Read and coworkers compared isoflurane and sevoflurane as sole agents for anesthesia in six 1- to 3-month-old foals and noted no differences between the two agents in induction and recovery characteristics or times. Direct MAPs were low in both groups for the first 30 minutes after induction, with a mean of only 44 ± 7 mm Hg and 46 ± 8 mm Hg for sevoflurane and isoflurane, respectively, at 10 minutes. Although MAP improved between 30 and 60 minutes, the cardiac index remained low. The latter varied between 93 and 117 mL/kg per minute in both isoflurane- and sevoflurane-anesthetized foals, which represents approximately a 50% decrease compared with the mean values reported for conscious foals. The respiratory depressive effects of sevoflurane could not be assessed because intermittent positive pressure was used.

Inhalant agents seem suitable for maintenance of anesthesia, and using sedatives, tranquilizers, or analgesic agents decreases the minimum alveolar concentration, which may offset the cardiorespiratory depressant effects of the volatile agents. On the basis of the information available, all currently available inhalant agents are suitable for use in foals.

**ANALGESIA**

Pain has negative physiologic and psychological effects in all species and should be treated. There are very few studies on pain assessment in foals and few on the efficacy of analgesic agents. Traditionally, analgesia is provided by nonsteroidal anti-inflammatory agents (NSAIDs), opioids, α₂-agonists, and local anesthetics. A detailed review of analgesic drugs and techniques of pain management used in horses can be found in Chapter 23.

It is not unusual for foals to respond to pain more abruptly and profoundly than adults—for example, during the initial incision at the start of a surgical procedure—even when the anesthetic depth appears adequate. Dunlop remarked during a study that evaluated the anesthetic potency of isoflurane that foals were hyperresponsive to the initial noxious stimulus. To block the initial response to surgery, local infiltration of the surgical site with lidocaine or bupivacaine is a simple and effective technique, as these agents also provide some analgesia in the early postoperative period.

The agonist-antagonist opioid butorphanol has been used safely in foals and is given IV or IM (0.1 to 0.2 mg/kg). Morphine and fentanyl at dosages similar to those used in adults have been used, but there are no reports on the pharmacokinetics or pharmacodynamics of these drugs in foals.

Several pharmacokinetic studies of NSAIDs (including phenylbutazone, ibuprofen, ketoprofen, and flunixin meglumine) in foals have been published. Many of these were primarily aimed at the use of these drugs for their antidotoxen effect rather than as analgesics. There are differences in volume of distribution, half-life, and clearance for phenylbutazone (2.2 mg/kg IV) between foals and adults, with foals less than 24 hours old showing a reduced ability for drug elimination.

Potential side effects of these drugs include gastrointestinal ulceration, nephrotoxicity, and platelet dysfunction. High dosages (5 mg/kg twice daily for 7 days) of phenylbutazone did not produce clinical signs of renal or gastrointestinal disease, or changes in complete blood counts or clinical chemistry in healthy 7- to 10-day-old foals, but renal changes could be detected through premortem ultrasonic examination, and gastric ulcers and histologic changes in the kidneys were found at necropsy. In healthy 5- to 10-week-old foals, ibuprofen at dosages up to 25 mg/kg three times daily for 6 days produced no unwanted side effects, but the authors cautioned that this may not be true in foals with compromised renal function. In healthy 1-day-old foals, dosages of ketoprofen must be increased to 1.5 times the adult dosage of 2.2 mg/kg to achieve therapeutic plasma concentrations, but because of reduced elimination, dosing intervals may need to be lengthened. It is also suggested that the dosage of flunixin meglumine, like that of ketoprofen, be increased in 1-day-old foals but that the dosing interval be extended. However, when treating septic or dehydrated foals, further adjustments must be made. The pharmacokinetics of flunixin meglumine (1.1 mg/kg IV) are different in foals at 1 day of age, 10 to 11 days, and 27 to 28 days of age. Drug elimination was significantly decreased in the youngest foals, most likely because of decreased hepatic metabolism and renal clearance. Despite these
differences, dosages of up to 2.2 mg/kg given over 5 days in 2-day-old foals caused no clinical, complete blood count, clinical chemistry, or pathologic changes. These studies suggest that the use of NSAIDs to treat acute perioperative pain in young foals should be safe and effective, but care should be taken in compromised foals.

**MONITORING AND INTRAOPERATIVE CARE**

Monitor is derived from the Latin word monere, which means “one that warns.” Monitoring vital functions in anesthetized foals is essential for a successful outcome, but monitoring equipment displays only numbers, and the anesthetist must know what values are normal and how to intervene if aberrations occur. For these reasons, it is important to be familiar with the physiologic data of neonatal foals described earlier.

Many of the techniques described for monitoring critically ill newborn foals, reviewed in depth by Corley,32,60 apply to anesthetized foals. During anesthesia, ventilation and oxygenation must be maintained, and therefore these variables must be monitored. Optimizing organ perfusion is a primary goal of the anesthetist, but perfusion per se is difficult to measure. Indirect markers of perfusion include cardiac output, blood pressure, urine output, and blood lactate values. Hypothermia has far-reaching deleterious effects, so body temperature should be closely monitored and active warming techniques employed. Foals may be susceptible to hypoglycemia, so blood glucose should be monitored.

**Cardiovascular Monitoring**

Cardiac output is the parameter that most accurately assesses cardiovascular function, but its measurement has until now been restricted to the research arena because of the technical challenges and dangers associated with cardiac catheterization, which include endocardial damage. New, less invasive technology that requires only a venous and a peripheral arterial catheter and lithium as a marker has revolutionized cardiovascular monitoring, making it the only validated technology that requires only a venous and a peripheral arterial catheter and lithium as a marker has revolutionized cardiovascular function, but its measurement has until now been restricted to the research arena because of the technical challenges and dangers associated with cardiac catheterization, which include endocardial damage. New, less invasive technology that requires only a venous and a peripheral arterial catheter and lithium as a marker has revolutionized cardiovascular monitoring, making it the only validated technique currently suitable for clinical use.32,62 This technique, termed lithium dilution (LiDCO Ltd, Cambridge, United Kingdom), is commercially available. Even more recently, a noninvasive cardiac output technique (NICCO, Novametrix, Wallingford, Conn) based on the Fick principle and partial rebreathing of CO₂ has performed well when compared with the lithium dilution technique in dogs,35 and it is being evaluated in neonatal foals (personal communication, A. Valverde, 2004). This technology can be used only in intubated animals, but because nasotracheal intubation is easily performed,38 it may be adaptable to conscious foals.

Cardiac output monitoring is invaluable in critically ill foals in the perioperative period. It allows the anesthetists to make prompt and appropriate treatment decisions and to monitor the response to fluid therapy, inotropes, or vasopressors. Normal values were discussed earlier in this chapter.

**Blood pressure** can be measured directly or indirectly and provides useful information on cardiovascular status, provided the clinician understands the correlation of cardiac output, systemic vascular resistance, and blood pressure, and is aware of the age-related changes in blood pressure. Direct measurement requires insertion of an arterial catheter (with all the associated problems discussed later in this chapter), and for this reason indirect methods are often used. The ultrasonic Doppler technique using a tail cuff as described by Lombard and coworkers32 was not validated against a direct blood pressure measurement and may have underestimated the blood pressure of neonatal foals. An electronic sphygmomanometer gave consistently lower readings than directly measured blood pressure in anesthetized pony foals,13 but the authors felt it was sufficiently accurate if a correction factor was used.

More recently, the accuracy of an indirect oscillometric monitor (ProFaq Encore 206EL, Protocol Systems, Inc, Beaverton, Ore) has been reported in both awake and anesthetized foals.13 There was good agreement between this technique (cuff placed around the tail) and direct measurement (greater metatarsal artery) for mean and diastolic blood pressure, but agreement was less satisfactory for systolic blood pressure. MAP is more clinically relevant, as this is a better predictor of organ perfusion. The authors recommended a ratio of cuff bladder width to tail girth of 1:2.8, and in practical terms, a 52-mm bladder was suitable for foals aged 1 to 2 days and weighing 44 to 68 kg.

On the basis of published results,13,14 a MAP of 60 mm Hg or below should prompt the clinician to intervene. Corley suggests that supportive therapy be initiated at an MAP of 69 mm Hg and published data indicating that MAPs less than 60 mm Hg in foals less than 1 week old are associated with a higher mortality rate.32 Foals with low blood pressure may require fluid therapy or inotropic support (see Chapter 1).

**Urine output** in foals is approximately 6 mL/kg per hour.21 Urine production reflects adequacy of perfusion, cardiovascular and hydration status, and renal function.32 Urine production can be measured after placing a urinary catheter using a sterile technique and attaching it to a closed collection system.32 Less than expected urine production should prompt the anesthetist to review the hydration and cardiovascular status of the foal.

**Respiratory Monitoring**

Arterial oxygen values in foals change with age and are lower than in adults. However, hypoxemia is a potential problem in awake and anesthetized neonatal foals but frequently goes unnoticed because clinical signs are nonspecific; therefore, reliable monitoring techniques are required. The gold standard is arterial blood gas measurement, but obtaining a sample by direct needle puncture may be technically difficult, maintaining an arterial catheter is challenging, and the site is a potential access for infection.61 In addition, only periodic information can be obtained. For these reasons, pulse oximetry has been evaluated in foals.32,64 Pulse oximetry is a continuous, noninvasive technique for estimating arterial oxygen saturation (SaO₂). Commercially
available monitors are inexpensive, but clinicians must be aware of their limitations. In anesthetized foals, the accuracy of one pulse oximeter (Nellcor N-200, Nellcor Puritan Bennett, Inc, Pleasanton, Calif) with three different transducers (fingertip, adhesive, and forehead reflectance types) placed at several sites (ear, lip, tongue, and ventral tail base) was evaluated.64 Pulse oximetry is a valuable technique, but the transducer type, placement site, and range of SaO2 values have a significant effect on reliability, so pulse oximetry should not totally replace arterial blood gas analysis. A fingertip-type transducer placed on the ear or tongue is the most clinically useful technique.

Carbon dioxide values reflect the balance between production (metabolic rate), cardiovascular function (transport of CO2 from tissues to the lungs), and elimination (ventilation). As previously discussed, increases in PaCO2 may have deleterious effects on CNS function. Elevated CO2 values may occur in weak and compromised foals, and most sedatives and general anesthetic agents produce respiratory depression and hyperventilation.

The partial pressure of arterial CO2 (PaCO2) is the most reliable indicator of pulmonary ventilation, but because of the difficulty in obtaining arterial blood samples, venous9 and end-tidal CO265 values have been studied in foals. End-tidal or end-expired CO2 (ETCO2) reflects alveolar CO2 tension, which in turn is closely related to arterial CO2, and is widely used as a noninvasive method for monitoring ventilation in anesthetized and intubated animals.66 Capnography refers to the graphic display of CO2 concentration over time and is preferred over capnometry, which provides the anesthetist with only a numerical display of CO2 concentrations. The attraction of capnography is the continuous display of information compared with intermittent blood gas analysis. Interpretation of the waveform not only provides information on patient factors but also alerts the anesthetist to equipment malfunction, such as kinked endotracheal tubes, airway obstruction, exhausted carbon dioxide absorbent, and incompetent one-way valves. Currently, there are two main types of capnograph available—the mainstream and the sidestream—and in dogs, the former was considered more accurate.65 However, the authors warned that under hypercapnic conditions (i.e., PaCO2 greater than 60 mm Hg), ETCO2 values do not accurately reflect the severity of hyperventilation, as determined by the gold standard of arterial CO2 measurement.67 The reliability of ETCO2 measurement in spontaneously breathing, isoflurane-anesthetized foals has been reported.65 A gradual increase in both PaCO2 and ETCO2 occurred over a 90-minute period, with arterial CO2 always greater than ETCO2.65 During the first 60 minutes, ETCO2 was a useful indicator. After 60 minutes, ETCO2 was not predictive and greatly underestimated arterial CO2 values—for example, at 90 minutes, the mean ETCO2 value was 63 mm Hg and PaCO2 was 78 mm Hg. The widening of the arterial to end-tidal gradient could be explained by hypoventilation and decreased pulmonary capillary perfusion of alveoli.65 As in other species,66 the limitations of capnography must be understood. Capnography may be useful for short anesthetic procedures, but it cannot totally replace blood gas analyses. This technology is primarily thought of as a respiratory monitor, but because carbon dioxide must be transported in blood from tissues to the lungs to be eliminated, sudden decreases in ETCO2 can reflect a cardiovascular crisis.

**Blood Glucose**

Both hypoglycemia and hyperglycemia are undesirable in anesthetized patients. In a conscious animal, hypoglycemia may result in seizure activity, coma, and CNS damage, all of which are masked by general anesthesia. In the past, the detrimental effects of hyperglycemia were underestimated, but human data strongly implicate elevated blood glucose values as a cause of increased postoperative infection and mortality.68-70

Problems associated with interpreting glucose results in foals include the analytical technique, sample site (venous, arterial, or capillary), and which references are used as normal values. The anesthetists must know whether the analytical technique they use measures plasma, serum, or whole blood glucose so that the correct reference data are used. For convenience, bed-side analyzers are commonly used in the operating room. In dogs71 and foals,72 there are wide variations in the accuracy of commercially available portable blood glucose monitors. Cohn and coworkers73 concluded that up to 67% of clinical treatment decisions would have been erroneously altered had the clinician relied on results obtained from some portable blood glucose meters and, according to their study, a point-of-care analyzer (i-STAT portable clinical analyzer, Heska Corporation, Fort Collins, Colo) was the only acceptable portable method.71 To track trends accurately, blood samples should be collected from the same site and analyzed using the same technique. Healthy foals scheduled for short procedures are unlikely to have problems associated with blood glucose, but premature foals and sick foals, especially those that may be septic and those undergoing surgery lasting several hours, should be monitored. To preserve normoglycemia, foals should be allowed to suckle up until the time of anesthesia and allowed access to their mare’s milk as soon as possible after recovery.

**Body Temperature**

Foals are susceptible to heat loss because of their high ratio of surface area to body weight, and their lack of subcutaneous fat. Hypothermia decreases metabolism of anesthetic drugs, delays recovery, and results in postanesthetic shivering, which increases oxygen requirements. Very low heart rates (less than 60 beats per minute) associated with rectal temperatures less than 36 °C (less than 97°F)72 are detrimental to foals because their cardiac output is more dependent on heart rate than that of adults. Shivering is unpleasant and may increase postoperative pain because of involuntary muscle activity around surgical wounds. Although not well documented in the veterinary literature, intraoperative hypothermia interferes with clotting enzymes, causing increased blood loss in humans.73,74 Postoperative infections are increased and wound healing is delayed by hypothermia, because cold-induced vasoconstriction results in decreased wound perfusion and oxygen delivery. In addition, antibody and cell-mediated immune systems are depressed by low body temperatures.68-75 Core temper-
ature (at the esophagus, tympanic membrane, or pulmonary artery) is considered the most critical value, but in a clinical setting and in awake foals, it is impractical to obtain. For these reasons, peripheral or shell temperature, usually a rectal temperature, is measured. The relationship between core and peripheral temperature is not well documented in foals, but in anesthetized adult horses, rectal temperatures did accurately reflect core temperature.76

Preventing hypothermia is important and can be done using simple and relatively inexpensive techniques such as dry, light-weight blankets, circulating warm water blankets, and forced warm air devices (Bair Hugger Therapy, Arizant, Inc, Eden Prairie, Minn). Additionally, cold operating rooms and forced warm air devices (Bair Hugger Therapy, Arizant, Inc, Eden Prairie, Minn). Large volumes of saline should be avoided, as this can promote acidosis.78

Foals that are septic, have diarrhea, or have lost blood but require surgery should be rehydrated promptly treated. Foals up to 1 month of age. Neonates are less tolerant of blood loss and dehydration because of their cardiovascular physiology,79 so fluid status must be closely monitored and promptly treated. Fluids that are septic, have diarrhea, or have lost blood but require surgery should be rehydrated before they are anesthetized. Hypovolemia is best treated with balanced ionic crystalloid solutions such as Normosol-R, Plasmalyte, or lactated Ringer’s solution.79 Large volumes of saline should be avoided, as this can promote acidosis.78

The response to therapy can be assessed by measuring blood pressure, urine output, and, if the technology is available, blood lactate. During surgery, similar fluids should be administered to replace respiratory and evaporative losses as well as blood loss, although the actual fluid administration rate will vary with each individual case. For a healthy foal undergoing an elective procedure, 10 mL/kg per hour should be adequate. Foals with uroperitoneum and hyperkalemia require specific fluid therapy (see Chapter 3). If blood glucose monitoring indicates it, dextrose may be added to the intravenous fluids.

Colloids, including dextrans and hetastarch, may be required if total protein and albumin are low or if there is a poor response to crystalloid therapy. Hetastarch is readily available and frequently used in neonatal resuscitation at a dosage of 3 mL/kg body weight infused at a rate of 10 mL/kg per hour. Blood loss or anemia can be treated with cross-matched whole blood, but the use of polymerized bovine hemoglobin (Oxyglobin solution, Biopure Corporation, Cambridge, Mass) has been reported in adult horses and could be used in foals. In addition to providing hemoglobin for oxygen carriage, this product is a potent colloid (see Chapter 4).

**Blood Pressure Support**

During anesthesia, blood pressure can easily be measured. It is recommended that a mean arterial blood pressure of greater than 70 mm Hg be maintained at all times to ensure adequate organ perfusion. If hypotension occurs, the cause must be identified, and it may be hypovolemia, hemorrhage, decreased cardiac output, or vasodilation, or a combination of any of these. If fluid losses are thought to be the problem, they can be addressed as discussed earlier.

Bradyarrhythmia has a marked effect on cardiac output and blood pressure in foals because of their high heart rate and fixed stroke volume. One of the main causes of bradycardia is hypothermia, and this must be prevented or treated, because heart rate does not respond to anticholinergic therapy in this situation. Bradycardia may result from vagal stimulation such as bladder manipulation. Such stimuli should be stopped and anticholinergics (atropine or glycopyrrolate) may be required. Anesthetic agents, in particular the inhalant agents discussed previously, are potent cardiovascular depressants. For these reasons, the depth of anesthesia should be closely assessed and, if possible, the vaporizer setting decreased. In addition, the use of an anesthetic-sparing drug such as xylazine, acepromazine, and lidocaine (as an infusion) is recommended to reduce the requirement for inhalant agents.

Although inotropes and vaspressors may be used to increase blood pressure, the goal is to improve organ perfusion, so increasing cardiac output and blood flow should be the first line of treatment.80 Monitoring cardiac output is the ideal and, as described previously, clinically acceptable techniques are now available. Dobutamine is a widely used inotropic agent in equine anesthesia and effectively increases cardiac output. In 1-month-old isoflurane-anesthetized foals, 3 µg/kg per minute of dobutamine doubled the cardiac output by increasing both heart rate and stroke volume, whereas in adult horses the increase is primarily related to stroke volume. These differences between adults and foals are a result of the changing sympathetic and vagal control of the heart with age. Despite the increased cardiac output, mean blood pressure in dobutamine-treated foals increased only from 60 to 70 mm Hg because of a significant decrease in peripheral vascular resistance. Therefore, blood pressure readings may not reflect the benefits of dobutamine, and monitoring increases in heart rate and urine output may be useful when cardiac output cannot be measured.

**Vasopressor agents** such as epinephrine (adrenaline) and phenylephrine should be used with caution because they increase cardiac afterload, their effects may vary in different organs, and despite an increase in systemic blood pressure, perfusion of the gastrointestinal tract and kidneys can be severely compromised.81 Vasopressin is receiving a lot of attention as a therapeutic agent in nonresponsive vasodilatory shock, and it has been used in foals, but its place in treatment of the critically ill and anesthetized foal will not be clear until further studies are conducted. Vasopressors should be used only when the blood pressure has not responded to other therapies. A comprehensive discussion of inotropes and vasopressors is outside the scope of this chapter and the reader is directed to the reviews by Corley.82,83

**RECOVERY**

Foals should be allowed to recover in a dry, warm environment, and they should be propped up in sternal recumbency to optimize their Pao2. If they shiver, supple-
mental oxygen should be provided to prevent hypoxemia. When they can be assisted to stand, foals should be reunited with their dam and allowed to suckle to maintain their fluid and caloric intake and to reestablish maternal bonding.

NEW TECHNIQUES AND CHALLENGES

Two techniques that require new anesthetic skills and knowledge are MRI and laparoscopic surgery. Neurologic disorders are common in foals, but until recently diagnosis has been hampered by the inability to image the brain. MRI is considered the diagnostic technique of choice for many CNS disorders and has become increasingly accessible to veterinarians over the past few years. The challenges of anesthesia in an MRI unit include working in a confined space with limited access to the patient and the incompatibility of conventional anesthetic equipment with the magnetic field and radiofrequency pulses. If inhalant anesthesia is used, the ferrous material in anesthesia machines must be replaced or the equipment adapted so that the machine remains outside the critical Gauss line (magnetic flux density). Alternatively, special MRI-compatible equipment must be purchased, and this option may not be practical for veterinary clinics. However, a more practical alternative is TIVA. In both situations, monitoring equipment must be chosen and used carefully to prevent patient burns and interference with the image. Excellent guidelines for anesthesia and monitoring in an MRI unit can be found at the website of the Anesthesia Patient Safety Foundation (www.apsf.org/index.php).

Chaffin and colleagues described an anesthetic technique suitable for MRI in neonatal (3-6 days of age) foals. Xylazine (0.5 mg/kg IV) was followed 5 minutes later by a bolus of propofol (0.2 to 0.4 mg/kg IV). After endotracheal intubation, a constant rate infusion of propofol (0.2 to 0.4 mg/kg) was started, and the rate was adjusted up or down depending on the depth of anesthesia. Oxygen was insufflated through the endotracheal tube using a long non-rebreathing (Bain) circuit attached to an oxygen supply outside the MRI chamber. For reasons previously discussed, PACO₂ should be monitored in compromised foals, and controlled ventilation is required to avoid the hypercapnia that occurs in spontaneously breathing foals during propofol anesthesia. Ventilation can be assisted in an MRI unit using an Ambu bag attached to the endotracheal tube, or manual ventilation with a bag attached to the breathing circuit. An oscillometric blood pressure monitor can be placed outside the magnetic field and attached by a long cable.

Laparoscopic surgery under general anesthesia has been reported for resection of umbilical structures and ruptured bladder repair in foals. (see Chapter 71). Advantages may include better visibility of intra-abdominal structures and less postoperative soft tissue swelling and discomfort. However, the effects of insufflation with carbon dioxide, abdominal distention, the Trendelenburg position, and longer anesthesia time must also be considered. In adult horses, CO₂ insufflation produced hypercapnia, acidosis, and an increase in cardiac work. In foals, no anesthetic-related complications were noted during or after laparoscopy, but the cardiopulmonary changes associated with this technique have not been critically evaluated in this patient population. It would be prudent to monitor PACO₂ and cardiovascular function closely during this procedure.

In conclusion, anesthetizing foals can be a challenge. However, it should be possible to decrease the currently unacceptable fatality rate in this group of patients. The clinician should have knowledge of foals’ unique physiology, age-specific pharmacologic data, evidence-based studies of anesthetic risk factors, and emerging technology (in particular, measurement of cardiac output).

CHAPTER 22

Recovery from Anesthesia
Regula Bettschart-Wolfensberger

Recovery is one of the most critical phases of equine anesthesia. Recent results from a multicenter prospective study of equine anesthetic fatalities reported that 23% of all non-survivors sustained inoperable orthopedic lesions during recovery.1 Because of the size and temperament of the horse, it is not possible to continue full monitoring, and mechanical ventilation during recovery and even fluid administration are discontinued in most cases. Significant problems such as hypoxemia or hypotension that may develop can be recognized only in severe cases. Once the horse starts to wake up, intervention is dangerous for personnel and, depending on the size of the horse and its temperament, often simply impossible. This chapter describes all aspects of recovery from anesthesia in horses.

MANAGEMENT OF HORSES DURING RECOVERY

General Aspects

During recovery, external stimuli (noise, bright light, physical stimuli) should be minimized. The horse’s head should be protected by a padded head cover. The recovery box should have a padded floor and walls. Ideally, the box would have an octagonal shape to prevent horses from being trapped in the corners. In some clinics, horses are placed on heavy foam pads for the recovery. These pads prevent the patients from making premature attempts to rise, because it takes a controlled and coordinated effort to "get out" of them and attain sternal recumbency. Frequently, human assistance is necessary to roll them from the mattress onto the recovery box floor. Because the patients cannot leave the mattress too early, there is additional time for inhalant anesthetic to be exhaled, which eventually results in a smoother recovery. Soft mattresses may also prevent nerve damage in cases of prolonged recovery. Depending on the nature of the surgery, the premises, and the personal preferences of anesthetists and surgeons involved, assistance during recovery (ropes, slings, hoists) may be desirable.2 Sling assistance is sometimes (6%) not well tolerated, and to prevent self-inflicted injury, the patients may have to be re-anesthetized. Fracture patients are most successfully recovered in a hydro pool (my personal experience).

In the early stages of recovery, an anesthetist should stay with the horse. Thereafter, continuous observation of the horse will reveal problems at an early stage, allowing imme-

### MANAGEMENT OF HORSES DURING RECOVERY

#### General Aspects

During recovery, external stimuli (noise, bright light, physical stimuli) should be minimized. The horse’s head should be protected by a padded head cover. The recovery box should have a padded floor and walls. Ideally, the box would have an octagonal shape to prevent horses from being trapped in the corners. In some clinics, horses are placed on heavy foam pads for the recovery. These pads prevent the patients from making premature attempts to rise, because it takes a controlled and coordinated effort to “get out” of them and attain sternal recumbency. Frequently, human assistance is necessary to roll them from the mattress onto the recovery box floor. Because the patients cannot leave the mattress too early, there is additional time for inhalant anesthetic to be exhaled, which eventually results in a smoother recovery. Soft mattresses may also prevent nerve damage in cases of prolonged recovery. Depending on the nature of the surgery, the premises, and the personal preferences of anesthetists and surgeons involved, assistance during recovery (ropes, slings, hoists) may be desirable. Sling assistance is sometimes (6%) not well tolerated, and to prevent self-inflicted injury, the patients may have to be re-anesthetized. Fracture patients are most successfully recovered in a hydro pool (my personal experience).

In the early stages of recovery, an anesthetist should stay with the horse. Thereafter, continuous observation of the horse will reveal problems at an early stage, allowing imme-
sitive intervention. Ideally, horses remain recumbent for at least 20 minutes and then roll into sternal recumbency for another 10 to 20 minutes. The attainment of sternal recumbency is associated with the restoration of more normal breathing patterns, and it reduces ventilation-perfusion mismatching in the lung, which should improve oxygenation. Horses that rest in sternal recumbency prior to attempting to stand usually then stand without complication. They recover best if they are allowed to exhale all of the volatile anesthetic agent before trying to stand and thus should not be stimulated to get up too soon. If a horse has not attempted to stand within 60 minutes after the end of anesthesia and is still in lateral recumbency, stimulation may be appropriate. If it is reluctant to get up, its status must be reevaluated and any problems treated.

For any surgery longer than 1 hour, the use of a urinary catheter is recommended, as it prevents overdentention of the bladder, which is uncomfortable for the horse. Without a urinary catheter, a horse often tries to get up before it is ready to do so. As soon as it is standing, despite being ataxic, it will try to urinate. This can represent a considerable risk, as the floor can become slippery and the horse may lose its balance and injure itself.

**Maintenance of Adequate Respiration during Recovery**

Insufflation of oxygen (15 L/min per 500 kg), first via the endotracheal tube and after extubation via nasal tubes or directly into the nasal cavity, helps to reduce the development of hypoxemia. If apnea is present, the use of a demand valve helps to ventilate the horse until spontaneous respiration resumes. Short periods of apnea (3 to 5 minutes)—for example, during transport from the surgery suite to the recovery stall—are not harmful. One study demonstrated that mechanically ventilated, anesthetized horses maintain higher values for partial pressure of arterial oxygen (PaO₂) postoperatively during a brief period of apnea than horses weaned from the ventilator prior to disconnection.

Controversy exists as to the optimal point during recovery for removal of the endotracheal tube. Most anesthetists advocate the removal of the endotracheal tube once the horse is actively swallowing. The presence of an active swallowing reflex helps to ensure that fluid or gastric reflux is not aspirated and that the horse replaces its soft palate into the normal position. Others believe that the tube should be removed only once the horse is standing. Exubation while the horse is in lateral recumbency allows earlier identification of potential respiratory obstruction. The endotracheal tube is then easily reintroduced, and if necessary a tracheostomy can be performed, which would be very difficult in a standing horse with acute dyspnea.

Another reason to remove the endotracheal tube as soon as the horse is swallowing is that some horses will object to this foreign body once they regain consciousness. This negatively influences recovery because the animal may try to get up too early. Therefore, I prefer to remove the endotracheal tube prior to the horse’s regaining a standing position. An alternative to this approach is to remove the endotracheal tube once the swallowing reflex is regained, and to place a small endotracheal tube via the nares for recovery. This technique avoids the inadvertent damage to the endotracheal tube from the teeth and still maintains a patent airway (see later).

Most recumbent horses develop nasal edema, and because horses are obligate nasal breathers, this swelling will impair breathing after removal of the endotracheal tube. In severe cases, significant airway obstruction may occur. Transient airway obstruction during recovery can also be caused by a variety of other problems, such as laryngospasm, laryngeal hemiplegia, dorsal displacement of the soft palate, kinking of the head in a corner of the recovery box, or obstructing foreign bodies in the upper airways. Regardless of the cause, any airway obstruction may lead to pulmonary edema or pulmonary hemorrhage, resulting in cardiovascular collapse and death.

Phenylephrine (0.15%) can be instilled into the nares to decrease nasal congestion and help prevent obstruction after extubation. An alternative is to insert nasal tubes approximately 20 cm long into one or both nasal cavities. It is necessary to have various diameters available to fit a wide range of horses. Fractious animals find this tube in their nares uncomfortable, however, and I prefer the use of an anticongestant. To achieve optimal effect, the drops are instilled 10 minutes before extubation. If, despite the use of nasal drops, labored breathing or snoring occurs after extubation, nasal tubes should be inserted and the head extended with the tongue pulled out. Should this not result in normal regular breathing, other causes of airway obstruction should be investigated. Orotracheal intubation or a temporary tracheostomy may become inevitable in these cases.

**Management of Cardiovascular Function**

Administration of fluids, dobutamine, or other vasopressors is usually discontinued before recovery. All inhalation anesthetics and total intravenous anesthesia regimens depress cardiovascular function in a dose dependent manner. At the end of anesthesia, the administration of these agents is stopped. Modern anesthetics are relatively quickly exhaled or redistributed, and thus cardiovascular function improves rapidly during recovery, and it is usually not necessary to administer fluids in the recovery period. If horses suffer from severe blood loss or hypotension (possibly as a result of endotoxemia) during anesthesia, continuing fluid administration and inotropic support during recovery is advocated. Depending on the severity of the condition, such horses continue to lose fluid from their circulating volume and thus have problems in maintaining adequate cardiovascular function despite waning of the depressive effect of anesthetic agents. Such horses, especially if they are large, have great difficulty in getting up.

**FACTORS INFLUENCING RECOVERY**

**Severity of Surgery, Temperament of the Horse**

Under clinical circumstances, the quality of recovery and ultimate outcome correlate negatively with duration of anesthesia and severity of surgery. On the other hand, under experimental conditions, when horses were anesthetized with isoflurane or halothane but did not undergo...
surgery, the temperament of the individual was the major factor determining the quality of recovery. Therefore, it follows that recovery after surgery in some horses will correlate well with their temperaments.

**Inhalation Anesthetic**

Different inhalation anesthetics possess different physical properties (see Chapter 19). Blood gas solubility is the major determinant of the speed of action of an anesthetic and thus duration of recovery. With halothane, the relatively high rate of metabolism (about 20%), in comparison to isoflurane (about 0.2%) or sevoflurane (2% to 3%), may have an influence on the quality of recovery in compromised patients. An early report that investigated duration and quality of recovery after 2 hours of anesthesia showed that recovery after isoflurane anesthesia is quicker and of a better quality than after halothane anesthesia. After 3 hours of anesthesia, no difference in duration or quality of recovery was detected between isoflurane and halothane. In another report, the recoveries of horses with or without surgery with isoflurane or halothane were compared. These authors found no difference in the quality of recovery but reported shorter recoveries following isoflurane. This is in contrast to clinical studies that showed that recoveries with halothane are of better quality.

Another experimental study compared halothane, isoflurane, and sevoflurane and found that recovery quality was better with sevoflurane and halothane, and duration was shorter with sevoflurane and isoflurane. Comparison of recovery after just 90 minutes of isoflurane or sevoflurane anesthesia showed that horses recovered significantly quicker and better with sevoflurane than with isoflurane. To date, there are no reports that compare the quality of recovery of desflurane (the least soluble and therefore fastest-acting inhalant agent presently available) with other inhalant anesthetics. In one report investigating desflurane in ponies, it was stated that "recovery from anesthesia was very rapid, although the quality in the unrestrained ponies was unacceptable."

**Sedation, Analgesia**

Pain has a negative influence on recovery in horses. To prevent central and peripheral sensitization, analgesia should be addressed before and during the anesthetic period. To provide maximal analgesia for recovery, especially after long, major surgical procedures, some additional analgesia, preferably using a multimodal approach, should be provided (see Chapter 23) (Table 22-1). In a clinical study of 25 horses undergoing arthroscopy, the preoperative use of phenylbu-

---
tazone did not alter recovery time but did slightly improve recovery score compared with patients not receiving this nonsteroidal anti-inflammatory drug (NSAID). These results are somewhat in contrast to the previous statements, which advocated continuous administration of analgesics during anesthesia.

The use of opioids in horses is controversial because of the fear of excitement and because of the effect of the opioids on the gastrointestinal tract. Some authors have tried to show the benefit of using opioids for recovery, but have failed to do so, probably because too many other factors also influence this period. They were, however, able to show that opioids do not negatively influence and prolong recovery or result in an elevated PaCO$_2$ level compared with that in untreated horses. In my experience, every horse benefits from the administration of morphine (0.1 mg/kg IM) 10 minutes before disconnection from the inhalation anesthetic.

$\alpha_2$-Adrenoceptor agonists such as xylazine slightly prolong the recovery period. In clinical cases, this usually results in superior recoveries. The fact that $\alpha_2$-adrenoceptor agonists act not only as sedatives but also as analgesics certainly adds positively to the calming effect. Most authors advocate the use of 0.1 to 0.2 mg/kg xylazine IV; others use low doses of detomidine, romifidine, or medetomidine. Because $\alpha_2$-adrenoceptor agonists negatively influence cardiovascular function, the use of low doses of xylazine (especially in compromised patients) is probably safest, as its side effects are less severe and of shorter duration. The $\alpha_2$-adrenoceptor agonists should be administered only once the horse has recovered enough to walk on its own. If a horse shows brisk palpebral reflexes or even nystagmus, the dose should be reduced. During their arousal or as soon as they are standing, because the major benefit of recovery in a hydro pool is that self-inflicted trauma is minimized because the partially submerged horse struggles against the resistance of the water until it is fully capable of standing. For the people involved in recovery, there is minimal danger while the horse is inside the pool. The critical phase is the removal of the horse from the pool. There are two different systems. At the University of Pennsylvania’s New Bolton Center, the horses are secured in a raft inside a round pool. The raft contains a sleeve for each leg and a flotation ring that has supports for the head. With this design, the horse has only minimal contact with the water. However, the stabilization of the horse inside such a pool can be difficult and requires several people during the entire recovery period. Removing the horses from this pool requires them to be lifted out of the raft by a sling attached to an overhead hoist (Fig. 22-3). In this critical phase, if horses do not cooperate, injuries might occur. It may be necessary to implement short-term sedation or anesthesia until the horse is safely in a stall.

Another hydro pool system has been designed to facilitate the process of getting the horse out of the water. The pool has a rectangular shape with the following measurements: 3.5 m long, 1.2 m wide, 2.5 m deep. The water is heated to 38°C and continuously filtered to remove dirt.

**Pool Recovery**

The major benefit of recovery in a hydro pool is that self-inflicted trauma is minimized because the partially submerged horse struggles against the resistance of the water until it is fully capable of standing. For the people involved in recovery, there is minimal danger while the horse is inside the pool. The critical phase is the removal of the horse from the pool. There are two different systems. At the University of Pennsylvania’s New Bolton Center, the horses are secured in a raft inside a round pool. The raft contains a sleeve for each leg and a flotation ring that has supports for the head. With this design, the horse has only minimal contact with the water. However, the stabilization of the horse inside such a pool can be difficult and requires several people during the entire recovery period. Removing the horses from this pool requires them to be lifted out of the raft by a sling attached to an overhead hoist (Fig. 22-3). In this critical phase, if horses do not cooperate, injuries might occur. It may be necessary to implement short-term sedation or anesthesia until the horse is safely in a stall.

**Recovery Stall Design and Construction**

Although there is no literature comparing the influence of different types of recovery stalls on fatality rates, most anesthetists agree on a number of important design features for recovery stalls. First of all, the recovery box should not be too large; this allows the horses to lean against the walls during their arousal or as soon as they are standing, because most horses show some degree of ataxia immediately after recovery. Ideally, the angles between walls are greater than 90 degrees (Fig. 22-1) to prevent horses getting trapped in a corner with their head in a kinked position. Padding of walls and floor is most important. Floors should provide secure footing with a surface that is not slippery, even when wet (urine, blood, excessive sweating, obstetrical lubricant). On the other hand, the surface must be soft enough to prevent abrasion injuries if horses fall during recovery. Last but not least, the padding should be easy to clean. Linatex (Four D Rubber Co, Ltd, Heanor, Derbyshire, UK) is a commercially available surface providing these qualities.

A recovery stall should also have metal rings (for attaching ropes), an oxygen supply, heating, air conditioning, lights that can be dimmed, a hoist, and easy access for recovery personnel in case of an emergency. Figure 22-2 shows a design for a recovery stall that allows intervention and help for the horse from outside the box, thereby minimizing the risk of injury to people. The ideal size of a recovery box depends on the horse’s size. The best option is to have several of different sizes. The size of the box in Figures 22-1 and 22-2 has proved optimal for horses ranging in size from 400 to 800 kg.
Additionally, bacterial contamination is minimized by passing the water through an ultraviolet filter. Because the horse is immersed in the water, it is impossible to totally prevent exposure of the surgical site to water, so application of a routine bandage for recovery is contraindicated. The wound is covered with an Ioban bandage (Ioban 2, 3M Health Care, St. Paul, Minn) and additional linear application of cyanoacrylate (superglue) around the entire incision. The Ioban sheet is further protected by an elastic adhesive tape.

The horse is placed inside the pool restrained by a sling or a net designed for the helicopter rescue of horses (Fig. 22-4). At that time, the scissor table installed within the pool is collapsed all the way to the bottom of the tank. While the horse is unconscious, its head is supported by a floating mattress. The horse is maintained in a sternal position in the
water. The head is secured in a vertical position by several ropes attached to metal bars on the sides of the pool (see Fig. 22-4). Once the horse starts to move, the table is elevated by a hydraulic system and the horse allowed to “feel” the table underneath its feet. After the patient has stood securely on all four feet in the water for some time, the table is elevated, pushing the horse up to the level of the room floor (Fig. 22-5). The sling is subsequently removed, the bandage removed, the surgical site prepared aseptically, a bandage reapplied, and once ready, the horse is walked into the recovery box, where it is allowed to dry under an infrared solarium.

This type of hydro pool was originally designed in California and has since been used regularly at Washington State University, Del Mar Race Track, and at the Vetsuisse Faculty University of Zurich, Switzerland. A report on the use of this type of recovery pool on 60 horses documented the following: mean anesthesia time, 182 minutes; mean time in the pool, 108 minutes (range 20 to 270 minutes). Furthermore, three horses showed severe lung edema (one of them died), two horses showed multiple skin abrasions from violent attempts to leave the pool during recovery, two horses showed incisional infections, and one horse developed septic arthritis following stifle joint surgery. These results demonstrate that hydro pool recovery is not risk free, but that it is a relatively safe option when a difficult recovery is anticipated.

During hydro pool recovery, extrathoracic and pulmonary pressures are increased, which may contribute to an increased incidence of pulmonary edema during anesthetic recovery. To minimize the likelihood of edema formation, all anesthetized horses in Zurich are treated with hetastarch (10%, 4 L/500 kg IV, in addition to Ringer’s lactate) to maintain plasma oncotic pressure during hydro pool recovery. Furthermore, acepromazine (0.03 mg/kg) is administered (IM) to produce peripheral vasodilatation and improve perfusion. The administration of acepromazine also provides some calming effect during recovery, without causing ataxia. Supplemental oxygen has decreased the incidence of edema at Washington State. As with any surgery, it is very important to provide multimodal analgesia to optimize recovery quality before hydro pool recovery. For any orthopedic surgery, I advocate the presurgical administration of phenylbutazone, α2-agonists, and possibly opioids (e.g., morphine 0.1 to 0.2 mg/kg IM); the intraoperative use of a balanced anesthesia regimen (e.g., isoflurane in oxygen + 3.5 mcg/kg per hour medetomidine IV); plus additional analgesia for recovery (e.g., 2 mcg/kg medetomidine IV + 0.1 mg/kg morphine IM). The use of an α2-agonist such as medetomidine for recovery is advantageous because it provides analgesia as well as sedation. Using this management protocol, lung edema has not occurred in 19 consecutive pool recoveries.

**PROBLEMS ENCOUNTERED DURING RECOVERY**

**Reluctance or Inability to Stand**

Most problems that become evident during recovery have developed during anesthesia. Hypotension (resulting in poor muscle perfusion), hypoxemia, and malpositioning on the surgery table are the major factors that result in the problems encountered during recovery in horses. Possible causes of prolonged recoveries follow.

**Myopathies**

Myopathies may affect single groups of muscles or they can occur in a generalized form. Myopathies occur most frequently if hypotension (blood pressure less than
70 mm Hg) is present for more than 15 minutes or anesthesia time exceeds 3 hours.38,39 Affected muscles are swollen to different degrees and are very painful. Depending on the severity of the myopathy, horses may be unable to stand. Therapy of the acute phase is supportive and symptomatic and should aim at reducing pain, swelling, and anxiety. NSAIDs, opioids, \( \alpha_2 \)-agonists, and, in severe cases, dimethyl sulfoxide (DMSO), dantrolene sodium, and corticosteroids should be administered. A small dose of acepromazine (0.02 to 0.03 mg/kg IM) may help to calm the horse and to improve peripheral perfusion, but this should be administered only if no major cardiovascular disturbances are present. As long as the horses are recumbent, oxygen should be administered via nasal tubes or directly into the nasal cavity. Ringer’s lactate solution or other balanced electrolyte solutions should be infused to help maintain cardiovascular function. In excited horses, the most important factor is to calm them, as repeated attempts to stand up exhaust the horse and the likelihood of a catastrophic injury increases. Head and tail ropes help the horse to lift its weight when getting up and provide some stability, because most affected horses show some degree of ataxia. Be aware that some horses resent the pull on the tail and abandon attempts to get on their feet.

Once the horse is standing, the major life-threatening problem is myoglobinuria resulting in kidney dysfunction. Appropriate fluid administration (to ensure maintenance of urine output) and monitoring of urine production are mandatory. Physiotherapy and infrared light may help the horse to relax its muscles and thus will reduce suffering.

**Neuropathies**

Neuropathies that impair recovery include femoral nerve paralysis, radial or brachial nerve paralysis, peroneal nerve paralysis, and hemorrhagic myelopathy. Neuropathies can also be accompanied by myopathies, and vice versa. Horses suffering from neuropathies of single nerves are not at high risk as horses suffering from severe myopathies, but the risk of fractures during recovery is relatively high in all horses with neurologic weakness. Horses are often unable to cope with paralyzed extremities: they get excited and injure horses with neurologic weakness. Horses are often unable to get up and provide some stability, because most affected horses show some degree of ataxia. Be aware that some horses resent the pull on the tail and abandon attempts to get on their feet.

Once the horse is standing, the major life-threatening problem is myoglobinuria resulting in kidney dysfunction. Appropriate fluid administration (to ensure maintenance of urine output) and monitoring of urine production are mandatory. Physiotherapy and infrared light may help the horse to relax its muscles and thus will reduce suffering.

**REFERENCES**

A discussion of equine pain and its relief must encompass the underlying neurophysiology of each type of pain; the mode of action of, indications for, and side effects of available drugs and analgesic techniques; and the current and rapidly expanding amount of evidence-based information.

**PHYSIOLOGIC CONSEQUENCES OF PAIN**

Pain occurs in a conscious state and is an unpleasant sensory or emotional experience associated with actual or potential tissue damage. It is a consequence of ascending impulses mediated by nociceptive fibers. Physiologic responses occur at the level of the spinal cord and include increased sympathetic tone, vasoconstriction, and increased myocardial work, which may lead to oxygen debt and arrhythmias. Increased blood pressure can compromise delicate tissues and surgical procedures in areas such as the eye. Decreased gastrointestinal motility is a common complication of untreated pain in horses. Increased skeletal muscle tone occurs on a segmental level and can potentiate oxygen demand, metabolic acidosis, and muscle spasms, which can augment pain. Muscle tension can also lead to abdominal splinting, reluctance to cough, hypoventilation, atelectasis, and hypoxemia.

The stress response or neuroendocrine response to pain can be dramatic, as is well documented in horses. Nociception stimulates adrenocorticotropic hormone (ACTH), cortisol, and renin/angiotensin II; it decreases insulin and testosterone; and it can interfere with osteoblastic and fibroblastic activity and subsequent healing. Metabolic responses include sodium and water retention, hyperglycemia, lipolysis, and catabolism. Central responses such as fear and anxiety can promote further sympathetic responses, resulting in a vicious cycle.

The historic argument against analgesic intervention is the loss of guarding behavior that protects the injured or surgical site. However, in addition to delaying healing, pain may cause anxiety and panic, leading to sudden and unbalanced movement, further harming an already injured animal. For example, horses with a closed fracture may panic, move frantically, and develop a catastrophic comminuted open fracture. A pain-free state is not necessarily ideal, but an acceptable level of comfort is the goal. Allowing pain to persist is no longer acceptable or necessary with the drugs and methods available to veterinarians today.

**PAIN ASSESSMENT**

Analgesia should be provided to reach a desired effect, but recognizing pain in horses is not always easy, especially in chronic pain states where signs may be subtle and their onset insidious. Electroencephalograms (EEG tracings) have been analyzed in horses under general anesthesia and correlated with a noxious stimulus. Pain-associated behaviors have been studied, but they are not the same in all horses because of differences in temperament, environment, and individual responses to drugs. Pain is not directly related to heart and respiratory rate, but these variables may be useful in an overall assessment of a patient.

Behaviors that strongly indicate pain include lip-curling, inappetence, sham eating, lowered head, disinterest in surroundings, and staying at the back of the stall. In addition to these, the more overt behaviors of guarding the painful site, unusual postures, and aggression or complacency should be noted. Catecholamines and corticosteroids are indicators of stress, which is frequently a component of pain. Their measurement is not practical in a clinical setting, but they have been used as objective markers in research studies. Palpation and gait analysis are evaluation methods that are suitable in a clinical setting. To develop a treatment plan, the patient should be assessed and reassessed at regular intervals after initiating treatment. Assessment methods should be

consistent. Using an objective scoring system to record the patient’s response is perhaps most practical.

**Characterization of Pain States**

**Acute Pain**

Tissue damage and inflammation cause acute pain. This is perceived as sharp, shooting pain mediated by large, myelinated A-δ fibers. Local anesthetics block these fibers by inhibiting propagation of action potentials. The slower onset of deep aching pain is mediated by C-fibers, which are also stimulated by inflammation, and this type of pain is opioid responsive. Continued stimulation of the C-fibers causes central changes, loss of central inhibition, and hence pain awareness.6 Centrally located endogenous feedback neurotransmission loops to inhibit the transmission of nociceptive stimulation occurs (i.e., prior to the start of a surgical procedure), and by treating continuously and not allowing pain breakthrough.7 Fewer analgesic drugs are needed with this approach, and the benefit is fewer side effects. Put in practical terms, pain is easier to prevent than treat.

**Central Sensitization**

Acute pain and inflammation lead to upregulation of nociceptive pathways, often within minutes of the inciting cause. Various types of pain states arise as a result of the plasticity of the nervous system. These pain states look different, require diverse treatment regimens, and represent central sensitization.5 Nociceptive input to the nervous system, because it is so plastic, results in rewiring of pathways and creates upregulated pain states. Hyperalgesia occurs when the magnitude of pain is greater than that expected from a nociceptive stimulus. Examples include pharyngitis causing pain when swallowing, or urinary tract inflammation causing pain during micturition. Hyperalgesia in the surrounding noninjured area is termed secondary hyperalgesia. Here, light touch stimulates low-threshold mechanoreceptors, which elicit a nociceptive stimulus. This alldynia occurs when an animal exhibits an exaggerated reaction after being touched in an area removed from the injury. Sympathetically maintained pain, which is not commonly acknowledged in veterinary medicine, is pain that depends on activity in the sympathetic nervous system. It can manifest in a variety of situations, such as chronic arthritis, soft tissue trauma, or neuropathies. Sympathetic pain is a subset of neuropathic pain. Persistent, spontaneous, phantom pain is pain perception resulting from central nociceptive activity without actual peripheral tissue damage. Chronic pain can include any one or a combination of these, and it may also have an acute component.

**Pain Modulation**

The body has protective mechanisms against pain that are centrally mediated, and we veterinarians try to emulate this endogenous network pharmacologically. Melzack and Wall first described the "gate theory" in 1965, in which ascending nociceptive transmission stimulates negative-feedback neurotransmission loops to inhibit the transmission and hence pain awareness.8 Centrally located endogenous opioids, norepinephrine, serotonin, and nicotinic cholinergic neurons, among many other neurotransmitters, contribute to pain inhibition.

**PRINCIPLES OF PAIN MANAGEMENT**

**Diagnosis**

Acute pain is often characterized by overt signs of pain, obvious tissue damage, response to palpation, and the horse’s history. Inflammation is usually obvious, or it occurs soon after the injury. If tissue damage, inflammation, or pain behavior is present, then pain sensitization should be assessed. Primary hyperalgesia may be tested by palpation over the area in question. Secondary hyperalgesia, or alldynia, can be tested by innocuous touch outside the region of the obvious cause of pain. The history of pain behavior or duration of the lesion may help define whether the pain is acute, or chronic with a superimposed acute component. Cause, severity, and duration should be documented.

**Preemptive Analgesia and Continuous Treatment**

Treatment of postoperative pain is facilitated by preventing the establishment of central pain sensitization. This is accomplished by administering analgesics before nociception occurs (i.e., prior to the start of a surgical procedure), and by treating continuously and not allowing pain breakthrough.7 Fewer analgesic drugs are needed with this approach, and the benefit is fewer side effects. Put in practical terms, pain is easier to prevent than treat.

**Multimodal and Synergistic Approach**

A balanced and layered approach to pain management is optimal (Box 23-1). To achieve synergism, prevention of nociceptive transmission at as many steps in the ascending pathway as possible should be attempted. Local anesthetics, opioids, anti-inflammatory agents, epidural drugs, and anxiolytics or sedatives should all be considered, depending on the type of pain already present or anticipated.

**Ancillary Pain Management**

Many factors other than simple tissue damage potentiate pain. The treatment of para-pain factors is important. Surgical methods may aid management—for example, reduction of impinging dorsal spinous processes causing back pain, arthrodesis for chronic osteoarthritis, and laparoscopic surgery to shorten postoperative recovery and healing time. Contact lenses may confer corneal ulcer pro-

selective than COX-2.10 In addition to the traditionally used most commonly used NSAID, Vedaprofen is licensed for use in the stomach.8 This may be the reason that newer-generation COX-2 specific antagonists have not been devoid of deleterious side effects.

Continuous Reevaluation

The analgesic treatment is only as good as the effect it produces. Because all animals respond differently (probably as a result of genetic variability) and because the neurophysiologic state is in flux, response to therapy must be carefully evaluated. Breakthrough pain and side effects of treatment must be monitored. A scoring system is recommended so that the horse’s comfort can be tracked as objectively as possible and to keep therapeutic goals in sight.

ANALGESIC DRUGS AND MODES OF ACTION
Nonsteroidal Anti-Inflammatory Drugs

Many painful conditions have an inflammatory component, and nonsteroidal anti-inflammatory drugs (NSAIDs) have historically been the foundation of equine pain management. NSAIDs inhibit the cyclooxygenase (COX) enzymes and decrease the release of prostaglandins and thromboxane, thereby interfering with the inflammatory cascade.5,9 Until recently, it was thought that a distinct delineation between the functions of the COX-1 and COX-2 enzymes existed. COX-1 was considered constitutive and responsible for gastrointestinal protection, renal arteriodilation, and platelet function, whereas COX-2 was thought to be responsible for the prostaglandins that mediate inflammation and pain.

Phenylbutazone and flunixin meglumine are potent COX-1 inhibitors, whereas carprofen is a weak COX-1 inhibitor10 that does not inhibit COX-2 in equine blood.11 Phenylbutazone is more effective for acute synovitis than ketoprofen at clinically relevant dosages12 and is still the most commonly used NSAID. Vardenprofen is licensed for use in horses in the United Kingdom and is more COX-1 selective than COX-2.10 In addition to the traditionally used drugs (phenylbutazone, flunixin meglumine, and ketoprofen), the newer NSAIDs carprofen, meloxicam, and etodolac are now available and have been used in horses, although pharmacokinetic and clinical data are lacking. Meloxicam has partial selectivity for COX-2.10 It is now known, however, that COX-2 is not only inducible but constitutive in some tissues, including the kidney, central nervous system, and stomach.6 This may be the reason that newer-generation COX-2 specific antagonists have not been devoid of deleterious side effects.

The actions of NSAIDs are complex and the therapeutic and toxic actions may also be in part caused by centrally mediated COX actions or COX-independent actions. Contraindications for any of the NSAIDs are preexisting bleeding disorders, renal or hepatic disease, and gastrointestinal ulceration. For a comprehensive review, see Moses and colleagues (2002).7

Opioids

Opioids other than butorphanol are not commonly used in horses, most likely because of the perceived side effects of excitatory behavior (rather than sedation) and decreased gastrointestinal motility. Excitatory effects of morphine and butorphanol at high dosages include restlessness, shivering, dangerously increased motor activity, ataxia, and sedation.13,14 These effects are uncommon when α₂-agonists or acepromazine is concurrently administered, or when the drugs are given to a horse in pain. Sellon and coworkers reported adverse gastrointestinal effects after a bolus injection of butorphanol.15 However, butorphanol can be given alone as an infusion for at least 24 hours with few side effects15 (Box 23-2): Opioid antagonists are being investigated for their usefulness in diminishing the gastrointestinal effects of many agonists without affecting analgesia.16

Opioids have a definite place in analgesia protocols and can be administered as boluses, as infusions, epidurally, intra-articularly, and transdermally. Not only do opioids produce an antinociceptive effect by inhibiting C-fiber transmission but they also decrease inflammatory pain by inhibiting substance P release from peptidergic neurons.17 Opioid receptors are present in the brain and spinal cord.18 When administered under general anesthesia, opioids produce analgesia and possible central nervous system stimulation at the same time, but they do not necessarily decrease the amount of inhalant necessary. In my personal experience, morphine (0.1 mg/kg intravenously) maintained a lighter anesthetic depth with less response to surgical stimulation and smoother recoveries but with arousal tendencies; also, in some horses, euphoria occurred. Mircica and colleagues reported that in a large clinical retrospective study, morphine given intraoperatively (0.1 to 0.17 mg/kg) did not result in more complications than if it were not given,19 demonstrating a lack of undesirable clinical side effects. However, another multicenter retrospective study showed that the postoperative incidence of colic was positively associated with morphine given at 0.1 mg/kg compared with either butorphanol or no opioid.20 Intramuscular morphine (0.66 mg/kg, higher than used clinically) produced effective analgesia for experimental superficial pain in ponies, whereas butorphanol intramuscularly (0.22 mg/kg) had little effect.13 Xylazine administered

intramuscularly (2.2 mg/kg) was more effective than either opioid.\textsuperscript{13} In a similar study, intravenous butorphanol (0.01 to 0.04 mg/kg) produced dosage-related superficial analgesia for 15 to 30 minutes.\textsuperscript{14} Butorphanol given intravenously (0.22 mg/kg) provided visceral analgesia for 60 minutes and was associated with ataxia but no excitement.\textsuperscript{2} At this dosage, the dysphoric effects are minimized when the opioid is given to a patient already in pain. Butorphanol given during surgery also reduces the need for additional doses of NSAIDS.\textsuperscript{22}

Peripheral opioid receptors are present in equine synovial tissue,\textsuperscript{23} which supports the practice of intra-articular opioid administration. In humans, intra-articular opioids decrease the need for systemic administration of postoperative analgesics,\textsuperscript{24} and perioperative analgesia shortens the time of return to mobility and normal range of motion.\textsuperscript{25} The small space and minimal vascularization of the joint prevents rapid uptake of opioid and allows a much longer duration of effect without systemic signs of sedation, or decreased gastrointestinal motility. A common clinical practice is to inject 0.1 mg/kg of morphine, diluted with saline or local anesthetic, into the joint at the end of surgery.

Transdermal fentanyl patches are useful as an adjunct in acute pain management, or as primary management of some pain states such as burns, laminitis, and pleuritis. Two or three patches (10 mg each) placed on a shaved area over the neck, antebrachium, or gaskin may confer 48 to 72 hours of continuous analgesia. Uptake occurs within 1 hour of application, and plasma levels decrease rapidly once the patches are removed.\textsuperscript{26} Replacement of the patches at the end of their life span should allow a constant systemic level to be maintained.

**Alpha-2 Agonists**

Xylazine (0.2 to 2.2 mg/kg), romifidine (80 to 120 µg/kg), detomidine (10 to 20 µg/kg), and medetomidine (4 to 7 µg/kg) are α₂-agonists commonly used for sedation and analgesia.\textsuperscript{27-29} Medetomidine infusions (see Box 23-2) have been used during general anesthesia\textsuperscript{30} and significantly decrease inhalant agent requirements, and recoveries are generally excellent (see Chapter 20). With α₂-agonists, sedation outlasts analgesia and one must be cognizant of this during invasive procedures or when treating pain.\textsuperscript{31} The cardiovascular side effects of bradycardia, bradyarrhythmias, increased vascular resistance, and decreased cardiac output\textsuperscript{32,33} seem to be well tolerated in healthy horses, but the impact of these have not been well studied in hypotensive, hypovolemic, or sick horses. The historical use and pharmacology of α₂-agonists were recently reviewed.\textsuperscript{34}

**Local Anesthetics**

Local anesthetics can be utilized topically, as specific nerve blocks, and by infiltration, either regionally or systemically. Sites for common perineural infiltration have been described in detail\textsuperscript{35} (see Chapter 74). In addition to being used for lameness evaluation, local anesthetic blocks can be used during standing surgery, to diminish postsurgical pain, to decrease the amount of inhalant agent needed during general anesthesia, and to comfort the horse during anesthetic recovery. The authors find that when proprioceptive deficits are prevented, perioperative local anesthesia of limbs results in a smoother recovery. Local anesthesia of normal, lacking a sensory component (e.g., the auriculo- palpebral nerve) may facilitate pain management as well as diagnosis by decreasing muscle tone and blepharospasm. Paravertebral thoracolumbar anesthesia can be performed to allow a surgical approach to the flank.\textsuperscript{36} Deeper nerve anesthesia is not commonly performed, but a sacroiliac joint block can be an effective management strategy for back pain.\textsuperscript{37} and cervical stellate ganglion blocks have been described for sympathetic pain disorders.\textsuperscript{38} Intrapleural, intercostal, dental, and pudendal local anesthetic blocks should also be considered when appropriate.

**Systemic Lidocaine Administration**

Intravenous lidocaine is used to treat ileus after abdominal surgery in horses.\textsuperscript{39} It significantly decreases the requirement for inhalant agents.\textsuperscript{40} Intravenous lidocaine can be a useful adjunct to other analgesic protocols. At clinically recommended dosages, it does not have the associated excitatory and gastrointestinal side effects of opioids or the profound sedating and cardiovascular depressant effects of α₂-agonists, and it is inexpensive. Infusions can be administered to both awake and anesthetized horses (see Box 23-2). Toxicity is easily recognized and managed. Sedation, muscle tremors, and progression to severe ataxia and collapse occur if the plasma concentrations are too high.\textsuperscript{41} If the infusion is discontinued, lidocaine is rapidly cleared and the effects quickly abate. Lidocaine has been used in conscious horses at a loading dosage of 1 to 5 mg/kg given over 10 to 20 minutes, followed by an infusion rate of 15 to 75 µg/kg per minute. Robertson and colleagues\textsuperscript{42} have shown that in normal horses, lidocaine increased the thermal threshold of skin, suggesting somatic analgesia, but it did not have an effect on visceral pain as measured by duodenal or rectal balloon distention. Further research on pharmacokinetics and dynamics in horses is ongoing, and more investigation is needed to clarify the role of lidocaine in equine analgesia.

**Drugs for the Treatment of Central Sensitization**

Once a sensitized state is suspected or diagnosed, therapy is aimed toward reducing the sensitization. Some examples of pain states that are related to sensitization include the chronic pain of osteoarthritis or laminitis, chronic wounds, and healing after orthopedic surgery.

NMDA antagonists, monoamine reuptake inhibitors, and anticonvulsants are the classes of drugs currently used to treat upregulated pain states. These drugs do not treat acute or ongoing pain but act to diminish sensitization and the abnormal neurologic states that cause hyperalgesia, referred pain, increased receptive fields, and allodynia. They are used as adjuncts to acute pain management. For many years, ketamine has been used as a component of anesthetic induction protocols and may have provided analgesia and prevented wind-up in addition to inducing dissociative anesthesia. As an NMDA receptor antagonist, ketamine can prevent or diminish central wind-up and self-propagation of nociceptive impulses. In humans, small subanesthetic dosages have been used in conjunction with opioids for management of chronic ongoing pain such as burns.
Ketamine infusions at dosages of 3 to 40 µg/kg per minute are used in small animals for treatment of pain sensitization and for intraoperative and postoperative pain management. Amantadine is an NMDA receptor antagonist that has been used in small animals, and it may have a role in equine pain management. Anticonvulsants such as gabapentin may have a future in equine analgesia, although phenytoin has been used in the past and may be much more economical.

Monoamine reuptake inhibitors such as the tricyclic antidepressants are used in human and small animal medicine for chronic pain at dosages that are less than those used for their antidepressant effects. There may also be a role in horses for these drugs. Tramadol, a weak opioid with non-opioid action, has been placed in the epidural space of horses. Its activity is in part from monoaminergic reuptake inhibition, which prevents ascending nociception. Reuptake inhibition allows an increase in central levels of catecholamines, which aid in negative feedback to nociceptive transmission. Many of the discussed drugs are not labeled for use in the horse, and species-specific pharmacokinetic data for them are not available.

INTRA-ARTICULAR ANALGESIA

As previously discussed, intra-articular opioids such as morphine can provide relief for up to 24 hours. Corticosteroids are primarily indicated for treatment of acute synovitis, although these drugs are also used for treatment of chronic lameness and osteoarthritis. Tramcinolone acetonide, methylprednisolone acetate, and betamethasone are frequently used intra-articularly for nonseptic joint disease, but the deleterious effects of intra-articular steroids must be considered. Hyaluronic acid and polysulfated glycosaminoglycan are used to promote joint health when the joints are the source of pain and lameness (see Chapter 84). Polysulfated glycosaminoglycan stimulates proteoglycan synthesis in chondrocyte monolayers, whereas betamethasone suppresses synthesis at high concentrations. Phenylbutazone increases sulfate uptake in chondrocyte cultures at low concentrations. Intra-articular local anesthetics such as lidocaine or bupivacaine can be administered for short-term relief.

EPIDURAL ANALGESIA

Epidural anesthesia is used to produce local anesthesia in the perineal and tail regions or in the hindlimbs. Local anesthetic drugs such as lidocaine, mevipacaine, and ropivacaine are commonly used for this purpose. Opioids, including morphine and fentanyl, are also used. α2-Antagonists such as xylazine and detomidine can be used in conjunction with opioids. Ketamine and tramadol have also been reported, alone or in combination with other more traditional analgesics.

The goal of using epidural analgesia differs from the goal of using anesthesia. Anesthesia is utilized with local anesthetics administered in such a volume that they inactivate action potentials in the spinal cord caudal to the branching of the sciatic and femoral nerves. Local anesthesia allows surgical incision to the perineal and tail area by blocking nociceptive, sensory, and motor transmission. Most anesthetics cause severe ataxia if the nerve blockade extends too far cranially, and this limits their use to perineal anesthesia. Analgesia, on the other hand, may include local anesthesia, but it has a much broader range of application. Indications include hindlimb, abdominal, thoracic, and sometimes front limb pain. Opioids, α2-antagonists, ketamine, and tramadol have been used clinically with minimal motor impairment. Systemic absorption and side effects vary depending on the solubility and other physical properties of the drug administered.

Drug combinations are most effective in the epidural space to provide analgesia. Local anesthetics are often combined with opioids or α2-agonists. Ropivacaine is a local anesthetic shown to block A-δ and C-fibers of nociception before compromising larger motor fibers; this results in less ataxia. Ropivacaine used together with fentanyl has been described.

For a surgical flank approach or for abdominal analgesia, subarachnoid analgesia can be performed. Segmental thoracolumbar analgesia with local anesthetic administered through a catheter has been well described in standing horses. Subarachnoid mevipacaine would facilitate standing surgical procedures such as ovariohysterectomy, laparoscopic cryptorchidectomy, and flank laparotomy, with onset of analgesia at 10 minutes and lasting 23 to 68 minutes. Epidural morphine (0.1 mg/kg) and epidural methadone (0.1 mg/kg) do not cause excitement, ataxia, or a decrease in depression. Morphine may be absorbed systemically and may cause mild sedation. Both of these drugs migrate cranially and cause ascending analgesia. However, methadone has a quicker onset and shorter duration, most likely because of its greater lipophilicity. Morphine could be used with local anesthetics, α2-agonists, or ketamine to create synergistic and longer-lasting analgesia. Butorphanol does not create significant epidural analgesia. Tramadol (1 mg/kg) can produce relatively long lasting ascending analgesia (up to 6½ hours) and can be combined with fentanyl to manage horses with severe intractable pain (of 12 to 24 hours' duration). Ketamine has commonly been used in human medicine both systemically and epidurally to decrease pain sensitization. In horses, epidural ketamine alone lasts only 30 to 90 minutes and may not confer surgical analgesia, but it is suitable when combined with morphine or xylazine to treat chronic or severe pain associated with laminitis and other painful orthopedic conditions. Surgical pain can be interrupted for a short duration by ketamine. Ketamine may also have local anesthetic properties and can be used for palmar digital nerve blocks in horses.

Placing an epidural catheter (Fig. 23-1) allows repeated dosing of analgesics for days to weeks. The drugs used for epidural analgesia and anesthesia are summarized in Table 23-1.

Complications

Injections into the epidural space should not be performed at a rate faster than 1 mL per 10 to 20 seconds, because rapid injections can cause ataxia and recumbency. Sedation can occur from systemic uptake of drugs. Morphine may cause other side effects, such as pruritus, and incorrectly placed epidural catheters may become knotted or contaminate the epidural space. Bleeding disorders, infection at the
placement site, and septicemia are contraindications for epidural catheter use.

COMPLEMENTARY THERAPY

Acupuncture

Acupuncture is becoming a respected and widely used form of therapy, especially for pain management in both human and veterinary medicine. In conjunction with electrical stimuli (electroacupuncture), it produces analgesia via nonopioid means as well as through release of β-endorphin into the cerebrospinal fluid. The effects are varied, and studies support endorphin release because the effects can be reversed with naloxone. Differences in response between sexes has been shown. Navicular pain has resolved and laminitis has been treated successfully. The International Veterinary Acupuncture Society (IVAS) and the Chi Institute are two well-respected veterinary training organizations for those interested in learning more about this treatment modality.

Other Treatment Modalities

Manual therapy, such as chiropractic manipulations, physical therapy, osteopathy, and massage, can facilitate a return to normal function. In chronic pain states when tissue damage has healed or scarred, tissue hypersensitivity and locomotion restriction may still exist. In addition to drugs

directed toward alleviating neuropathic pain. Joint and muscle manipulation can restore proprioceptive and mechanoreceptor input to normalize segmental and suprasegmental reflexes and decrease sensitized nociceptive input. Therapeutic ultrasound for soft tissue injuries has been shown to increase blood flow and decrease pain. These therapies have a place in intensive pain management situations as well as sports medicine. Magnetic, extracorporeal shockwave, and laser therapy are also management modalities of interest, and controlled studies in these fields are ongoing. Herbal therapy is backed by extensive clinical experience but not by widely published controlled studies. Good reviews of herbs used in equine pain management have been published.

Figure 23-2 shows a comprehensive approach to pain management.

NOVEL THERAPIES

Capsaicin ointment has local analgesic effects and can be considered for perineural treatment of laminitis, osteoarthritis, and any other painful situation that is amenable to topical analgesics. Use of capsaicin is not a new idea, as it was used in ancient times in the original form of hot chili peppers. Capsaicin is used to deplete substance P and decrease A-δ and C-fiber nociceptive transmission. In palmar digital skin application, it causes dramatic analgesia of the foot for up to 4 hours.

Transdermal delivery of analgesics to localized areas presents an interesting form of directed analgesia. Lidocaine (5%) patches (Lidoderm, Endo Pharmaceuticals, Chadds Ford, Pa) have provided promising results. Cathodic iontophoresis has the potential to deliver anionic anti-inflammatory drugs to superficial sites, although intra-articular sites may be too deep, as evidenced by work with ketoprofen by Eastman and coworkers. Other constant-rate drug delivery systems are being developed. Surpass (IDEXX Laboratories, Greensboro, NC) is a topical formulation of 1% diclofenac applied to joints for isolated anti-inflammatory effects. Nanotechnologic techniques are being used in the investigation and development of drug delivery methods.

FUTURE DEVELOPMENTS

Immune-modulating drugs such as rubeola virus immunomodulator for chronic myofascial pain have been described and utilized in veterinary clinical practice, although this has not been published in a peer-reviewed journal. Central nervous system immunomodulation holds promise as a therapeutic target for chronic pain and opioid tolerance. The vanilloid receptor VR-1 is a peripheral component of the nociceptive pathway, and it can be targeted to permanently remove pain but not sensation. Perhaps there will be a role in such conditions as laminitis or navicular disease. Controlled studies are ongoing.

Recent Advances in Anesthesia

56. Redua MA, Valadao CAA, Duque JC, et al: The pre-emptive effect of epidural ketamine on wound sensitivity in horses tested by using...

Skin lacerations and other traumatic injuries of the integument are frequently seen in equine practices and range from relatively minor cuts to severe, potentially debilitating injuries. The challenges facing the practitioner managing these injuries are numerous, and treatment is dictated by the nature and size of the wound, the area of the body on which the wound occurs, and several aspects of wound healing unique to horses. The age of the wound, integrity of the local blood supply, degree of contamination, location of the injury, skin loss, and local tissue damage must all be considered when deciding on the most appropriate method for managing a particular wound. In addition to biologic factors, the physical size of equine patients and the environment in which they are kept present unique management challenges not encountered in the treatment of soft tissue injuries in other species.

Primary, or even delayed primary, closure may not be a viable option, and many wounds are best treated by secondary closure or as open wounds. To get the best cosmetic and functional results, open granulating wounds should be managed in such a way as to allow maximal contraction and optimal epithelialization. Carefully planned reconstructive and skin mobilizing techniques can be used in conjunction with primary, delayed primary, or secondary wound closure, and as part of an overall strategy of open wound management to minimize the potential cosmetic and functional shortcomings of excessive epithelialization (scarring). Besides traumatic wounds, there are other clinical situations, such as the planned excision of skin lesions, in which reconstructive procedures can be used to facilitate closure of surgical incisions.

The overall objective in the management of any wound is to achieve a result that is as functional and as cosmetically appealing as possible. The benefits of successfully using reconstructive procedures in wound management include an increased percentage of the wound covered with full-thickness skin, improved cosmetic appearance and function, and a reduction of overall healing time.

The combination of skin loss and the amount of redundant or loose skin surrounding a wound has an obvious influence on the clinician’s ability to close a wound and the extent to which wound contraction will contribute to the final result. The effects of the location of the wound on the body as well as breed differences on wound healing in horses are well recognized, as is the influence of surrounding skin tension on wound contraction. Similarly, the extent to which some reconstructive and skin mobilization techniques can be used depends on the presence of adequate tissue surrounding the wound.

Financial and time constraints are often imposed on the practitioner, and it is advisable to spend time discussing the owner’s expectations, the possible complications, and the costs associated with these procedures before beginning. When these techniques are used, particularly in elective, cosmetic procedures, failures can result in significant client dissatisfaction. The application of reconstructive and mobilization techniques has not been studied in horses to the same extent as in other species.

Understanding the principles and limitations of reconstructive procedures, adhering to the basic principles of equine wound management, and providing appropriate postoperative care all contribute to a successful outcome.

Detailed descriptions of the vascular supply to the skin in humans and dogs have been the basis for significant advancement of cutaneous reconstructive procedures. A full appreciation of the normal anatomy and function of the cutaneous vascular supply, particularly as it pertains to the healing process, contributes to sound clinical judgment, allows the selection of appropriate surgical techniques, and provides an insight into the possible reasons for surgical failures. Two types of vessels supply the skin—musculocutaneous vessels, which are perforator vessels that pass through the body of underlying muscle, and direct cutaneous arteries, which reach the skin by passing through the fascial septa between muscle bodies. Direct cutaneous vessels run subdermally in the muscle and supply a larger area of skin than do musculocutaneous vessels.

In most animals with loose-fitting skin, the skin is supplied by direct cutaneous vasculature. These cutaneous vessels run parallel to the skin surface and are closely associated with the panniculus muscle in areas where this structure is present. In the distal extremities, where no panniculus muscle exists, the direct cutaneous arteries run beneath and parallel to the dermis.

The term angiosome has been applied to an area that is supplied by a single artery. A total of 374 such angiosomes...
have been plotted in humans. In a similar study in other mammals and vertebrates, the cutaneous perforator vessels were found to be larger and sparser in areas where skin was very mobile but smaller in diameter and more densely packed in areas where skin was less mobile. This finding was consistent in the species studied and, although horses were not included in the study, it seems reasonable to assume that a similar pattern exists in equine skin.

Smaller vessels branch off these cutaneous arteries and arborize in the dermis, forming three closely interconnecting plexuses—the deep subcutaneous plexus, the middle cutaneous plexus, and the superficial subpapillary plexus—which together supply the dermis and adnexal structures of the skin. The superficial plexus is an important component of the thermoregulatory system, and all three are crucial in maintaining the integrity of the blood supply and are thus of importance when manipulating skin in reconstructive procedures.

A number of skin flaps based on the major cutaneous arteries of the trunk are commonly used in dogs. These include axial pattern flaps, island arterial flaps, and vascularized free flaps. A skin flap based on the cutaneous portion of the caudal branch of the deep circumflex iliac artery has been described and used in experimental studies for a vascularized free tissue transfer in the horse. Although regional differences in blood supply and the influence this has on wound healing in horses is well recognized, more detailed descriptions of the vascular supply to the equine skin are required to expand our understanding and use of reconstructive procedures.

**PHYSICAL AND BIOMECHANICAL PROPERTIES OF SKIN**

The physical and biomechanical properties of skin are the focus of increasing attention in reconstructive surgery, and application of these characteristics is an integral part of many procedures in reconstructive surgery. Although many of the techniques have not been tested in horses, they provide some interesting potential opportunities in equine reconstructive surgery.

The biomechanical properties of skin are the product of three structural components: collagen fibers that impart strength, elastic fibers, and the ground substance (predominantly proteoglycans). Interactions between these components give skin its viscoelastic properties. It is important to note that these components vary considerably between individuals and between different sites of the body. In humans, they are known to be affected by aging, solar radiation, disease, and chemical and physical trauma. The effect of superficial hydration of the skin on its mechanical properties has potential benefits in reconstructive surgery. Twenty minutes after the application of wet paper towels, covered by a plastic wrap, a significant increase in the distensibility was seen, but the skin became more plastic in its behavior. This study concluded that the deep structures of the skin were unlikely to be affected by the short-term hydration and postulated that the contribution of the epidermis to the mechanical properties of skin may explain the mechanical differences seen between a pure collagen model and skin. The positive benefits of superficial hydration of the skin in a limited number of clinical cases supported the experimental observations.

**Tension**

The normal tension that exists in skin is a result of the elastic fibers in the dermis and is the reason skin edges retract when incised. In 1861, Professor Langer expanded on previous work and mapped out the so-called Langer’s lines of tension (cleavage lines, or “splittability” lines) over the surface of the human body. This work followed the unexpected observation that when skin was punctured by a conical instrument, an elliptical, not a circular, defect resulted. Langer’s lines were established in cadaveric studies and were referred to as lines of maximal tension, but Langer’s studies did not take into account body or limb position or movement. However, since skin is anisotropic, these tension lines are influenced by muscle contraction, movement of joints, and other external forces, and thus Langer’s lines are more accurately referred to as relaxed skin tension lines. Nonetheless, it is these tensile forces that result in the retraction of skin edges after an incision. Incisions made parallel to lines of maximal tension will gap to a lesser extent and heal with a finer scar than incisions made at right angles to them. Incisions made at right angles to lines of tension will heal with scars that, over time, become stretched and less cosmetically acceptable.

Skin extensibility is another important physical property of the dermis that is used to advantage in reconstructive surgery. Lines of maximal extensibility have been shown to run at right angles to Langer’s lines, which logically could also be referred to as lines of minimal extensibility. Pinching skin into folds at the site of a proposed reconstructive procedure can be used to roughly determine the extent of orientation of skin extensibility and to assess whether or not the edges of the remaining defect can be brought into apposition after excision of a lesion or the revision of a scar. When excising an elliptical piece of skin, closure is facilitated by ensuring that the long axis of the ellipse is aligned to Langer’s lines. Because the lines of maximal extensibility are at right angles to Langer’s lines, the width of the ellipse can be wider if the long axis is parallel rather than perpendicular to Langer’s lines. Tension lines and lines of extensibility in the human skin are well documented, and diagrams showing their locations can be found in most plastic and reconstructive surgery texts.

Tension lines have been described in dogs, but they have been investigated to only a very limited extent in the horse. Lines of maximal extensibility have been mapped for the equine carpus, which has given credence to the clinical practice of making longitudinal incisions over the dorsal aspect of the carpus. Diagrams showing the orientation of tension lines in the dog resemble the color patterns seen on the tiger and zebra, and it has been suggested that the lines of the skin color pattern in these animals closely mimic lines of tension. In the absence of detailed information, these generalities can be used to advantage in planning reconstructive procedures in...
horses. However, to make full use of such surgical procedures as Z- and W-plasties in the horse, a much greater understanding of the physical properties of the equine skin is required.

Creep and Stress Relaxation
As a result of its viscoelastic properties, skin demonstrates two related, time-dependent biomechanical properties referred to as creep and stress relaxation. Creep is the increase in length (strain) that occurs when a constant force (stress) is exerted on a piece of skin. Creep results from the normally convoluted collagen fibers becoming straightened and aligned in a parallel fashion. Water is displaced from the collagen network, and disruption of elastic fibers occurs. Stress relaxation, on the other hand, is the decrease in the stress that occurs when the strain imposed on a piece of skin is kept constant, which explains why the tension on a suture line decreases to some extent a few minutes to hours after surgery.

Mechanical creep must be differentiated from biologic creep, which is the generation of new tissue in response to chronic tension. Biologic creep occurs during pregnancy, as a result of obesity, or in association with clinical situations such as hernias and large skin tumors.

A number of surgical techniques in reconstructive surgery utilize these viscoelastic properties of skin; however, there are only limited documented accounts of the application of these procedures in horses. Used alone or in combination with the other techniques described in the following paragraphs, they provide interesting possibilities for the management and reconstruction of skin wounds in horses.

SKIN EXPANSION AND STRETCHING TECHNIQUES
Presuturing
Presuturing is a preoperative suturing technique to plicate skin over an area of proposed excision.16 The technique utilizes the mechanical creep properties of skin and in a pig model has been shown to decrease the tension required to close a standardized wound by 40%. When compared with simply undermining the surrounding skin, presuturing did result in some tissue gain and an initial decrease on closing tension, although this advantage diminished over time.15 In this study, it was concluded that the demonstrated progressive increase in water content of the tissue resulted in the skin’s becoming stiffer and thus harder to close. The duration of presuturing is thus important, and clinical observations in the horse support this. Where the preplaced sutures were left in place for 24 to 30 hours, moderate edema resulted that was not seen when the sutures were removed after 4 to 8 hours.16,17 Periods as short as 2 1/2 hours have been shown to be beneficial.18 Placement of the plicating sutures can be carried out under local anesthesia. Optimally, the sutures should be placed in the direction that will take greatest advantage of the inherent extensible nature of the skin. As discussed previously, although the lines of maximal extensibility have not been mapped out for the horse, sound clinical observation and assessing extensibility by pinching the skin into folds over the proposed area will provide useful information.

The original description of this procedure suggests that presuturing avoids the potential complications that can be associated with undermining.16 However, the combination of presuturing and undermining may provide additional advantages.

Intraoperative Tissue Expansion
Intraoperative tissue expansion has been advocated as a means of decreasing incision closure tension, and, since the original description of intraoperative sustained limited expansion,20 a number of synonyms for this strategy have developed, all of which imply a single-stage procedure involving the rapid expansion of the surrounding skin. The techniques for achieving this have varied from the manual application of traction using towel clamps applied to the skin edges, to the use of Foley catheters and the short-term subcutaneous implantation of other inflatable balloon devices.21 Variations in technique have been described ranging from tension being applied in three or four cycles of 3 to 5 minutes, to a single loading cycle applied for 20 minutes. The original explanation that this technique utilized the creep phenomenon has been challenged, and it has been suggested that this technique utilizes only the normal elastic properties of skin.22,23 Histologic studies support this, as none of the changes in the dermis associated with mechanical creep are seen with acute intraoperative tissue expansion, and although several studies have been designed to demonstrate the benefits of intraoperative expansion,24,25 other studies have concluded that it is in fact the undermining of the surrounding skin required for the placement of the inflatable balloons that accounts for the decrease in closing tensions.26,27 Intraoperative skin expansion relies on the inherent extensibility of the skin and, as previously mentioned, these properties vary at different locations on the body. Although there are no published reports of using this technique in equine reconstructive surgery, there are sufficient reports of the potential benefits in other species to justify considering...
this procedure as part of a strategy to manage tension across a wound closure.

External Skin-Stretching Devices

Externally applied devices designed to recruit skin from the surrounding area have been described.29,30 The successful use of a relatively simple system using adherent skin pads and elastic connecting cables has been described in dogs.30 The placement of the adherent pads relative to the skin edge can be varied according to the amount of skin recruitment required. By subjective assessment, a moderate amount of tension is applied on the cables and is increased every 6 to 8 hours. The greatest gains in recruitment of surrounding skin appeared to be achieved 48 to 72 hours after application. The technique was reported as being well tolerated, and no biologic complications were encountered with separation of the adhesive pads associated with excessive tension being the most common technical complication.

The suture tension adjustment reel (STAR) is an externally applied device that allows tension on a preplaced horizontal mattress suture to be adjusted after the knot has been tied.31 This device can be used preoperatively as an adjunct to the presuturing technique and has been advocated as a means of achieving intraoperative tissue expansion.

Elastomers

Studies in other species have shown encouraging results with the use of silicone elastomer tissue expanders in reconstructive procedures, but descriptions of the use of this technique in horses are limited.32 This procedure entails placing a silicone pouch under the intact skin immediately adjacent to the scar that is to be repaired. After the implant incision is healed, the pouch is expanded over a period of 4 to 7 days by the injection of small amounts of saline through an injection port, thereby stretching the overlying skin. The elastomers are available in various sizes and shapes to allow flexibility in the amount of tissue expansion. Once sufficient skin expansion has been achieved, the elastomer is removed and the expanded tissue is used to form a skin flap to cover the defect. This procedure takes advantage of both mechanical and biologic creep, and the microscopic changes seen in the skin are consistent with mechanical creep. In addition, new tissue is generated in response to the chronic forces.34

The use of expanders may be of substantial benefit where limited skin is available for reconstructive procedures. Canine studies have recorded increases of 35.9% and 37.3% in the surface areas of skin on the antebrachium and crus following controlled expansion.33 Other studies in dogs have shown that these are well tolerated and provided sufficient additional skin for the development of pedicle flaps to cover defects on the tarsus.34

Other advantages include similarity of the color and hair coverage of the donor skin to the surrounding area, the absence of a donor site defect, and the quality of the skin that is generated. The optimal inflation pressure of the elastomer has not been determined in large animals. In a canine study, 20 to 40 mm Hg was initially used, but pressures approaching capillary pressure have been shown to be safe.34 Excessive pressure can lead to ischemia and necrosis of the overlying skin. Skin color and transcutaneous partial pressure of oxygen have been used in human patients to monitor the integrity of the blood supply to the expanding skin.

In cattle, where the skin is thicker and stiffer, the increased pressure required resulted in rupture of the elastomer, suggesting that a more resilient device may be required for use in large animals.32 Random pattern flaps created from expanded skin have a longer survival rate than those raised from nonexpanded skin. When compared with controls, the survival length of delayed random pattern flaps and similar flaps raised from expanded skin was increased 73% and 117%, respectively. This increased viability is attributed to similar effects seen in the delay phenomenon.35,36

Histologic changes seen in expanded skin are consistent with mild inflammation that includes edema and the formation of a fibrous capsule around the expander.33,36 The initial thickening of the epidermis and thinning of the dermis seen immediately after expansion has been shown to return to normal 24 weeks after transfer of expanded skin in dogs, and similarly the capsule that forms around the expander disappears.37 However, this fibrous capsule results in an overall thickening of the raised flap and loss of elasticity of the expanded skin.34 This increased stiffness may compromise the surgeon’s ability to manipulate the flap in the reconstructive procedure. Removing this fibrous capsule may resolve this problem to some extent, and the effect of capsulectomy on the blood supply to the expanded skin has been investigated.38 Although some controversy surrounds this issue, it appears that removing or incising the capsule to facilitate advancement of the flap does not critically affect the survival of the expanded tissue.38

Complications include implant failure, wound dehiscence, and premature exposure of the expander necessitating its removal before adequate expansion had been achieved. Although more experience is required with the use of tissue expanders, they add an exciting new dimension to the treatment and repair of skin defects in horses.

SUTURES AND PATTERNS

The proper placement and use of appropriate suture patterns are important technical considerations in reconstructive surgery. The selection of a suture pattern is often based on personal preference; however, in some instances, there are definite advantages and disadvantages associated with particular patterns that should be taken into consideration. The choice of suture material is of less importance.39 Manipulation of the tissue when placing sutures should be performed asatraumatically as possible. If instruments are used to stabilize or manipulate the skin edges, crushing and abrading tissue, which is detrimental to future healing, should be avoided; using one’s gloved fingers is probably the least traumatic method. Most reconstructive procedures can be performed using a standard instrument set; however, the addition of a limited number of instruments will greatly assist the surgeon. The addition of sharp skin hooks or Lahey traction forceps aids in minimizing trauma when stabilizing tissue. Sterile Backhaus towel clamps are an acceptable alternative. Stabilization of the skin using an instrument that penetrates the tissue is less damaging to the skin and its microvasculature than using an instrument that has a crushing action.
To facilitate optimal healing, accurate apposition of the skin edges with minimal interference to the blood supply should be the goal when suturing wounds. The pattern and technique of suture placement, the number of sutures, and suture line support all play an important role in ensuring an optimal outcome.

The spacing of sutures plays an important role in maintaining optimal apposition of the skin edges. As a rule, sutures should be placed at a distance equal to the thickness of the skin itself. However, other factors, such as the tension on the wound edges and the thickness and stiffness of the skin, must also be taken into consideration. The collagenolytic and inflammatory processes that take place during early wound healing serve to weaken the suture-holding ability of skin, and as a result, sutures should be placed at a distance of at least 0.5 cm from the skin edge for improved security. Clinical experience with equine wounds treated by secondary closure shows that wound edges where newly epithelialized tissue exists have little or no holding strength, making it important to place the sutures well back from the skin edge to ensure optimal holding strength. In laboratory animals, the levels of matrix metalloproteinases (MMP) have been shown to be higher in keratinocytes during reepithelialization, and in a porcine model, the levels of these collagenolytic enzymes have also been shown to be higher and to persist longer in granulating wounds than in sutured wounds. Neutrophil-derived MMP has been associated with nonhealing wounds in human patients, and overexpression of this particular collagenase may be part of the pathogenesis of chronic ulcers. A sound working knowledge of the biology of wound healing improves clinical judgment and reduces the risk of failure of repair (see Chapter 5).

Sutures should be placed as close together as is necessary to achieve good approximation of skin edges. In human surgery, placing interrupted sutures 0.5 cm apart has been shown to give good tissue apposition and to minimize tension on individual sutures. The suggestion that the distance between individual sutures should be twice the thickness of the skin may apply, although in some instances, this procedure may result in an excessive number of sutures being used, leading to impaired healing as a result of excessive tissue reaction.

The tension applied when placing and tying skin sutures should be sufficient to appose the skin edges, but over-tightening of sutures can result in failure of the suture line. The overall tension on a suture is a combination of intrinsic and extrinsic tension. Intrinsic tension is the constricting effect within the suture loop, which, if excessive as a result of the suture being tied too tightly, causes strangulation of the blood supply to tissue within the loop of the suture. A higher degree of intrinsic tension can be generated with heavier suture material, and any postoperative swelling will increase the intrinsic tension of a suture. Extrinsic tension results from opposing forces exerted by the surrounding skin on the suture when drawing the skin edges together. Extrinsic tension is related to the size of the defect being sutured and to the amount of redundant or loose skin in the area. Tension on sutures can lead to tissue necrosis by interfering with local blood supply, increasing edema, and decreasing the oxygen supply to the skin. The clinical result of this can include wound dehiscence, sloughing of tissue, and delayed healing which, depending on the location of the suture line, may have catastrophic consequences.

Basic Suture Patterns

Simple Interrupted Sutures
Simple interrupted sutures are commonly used and give good tissue apposition, provided they are not placed too far back from the skin edge or pulled too tightly, which will cause inversion of the skin edges. Placement with slight inversion is preferred to inversion. A simple interrupted pattern also allows adjustments for good alignment of skin edges in irregularly shaped defects. If placed correctly, this pattern results in minimal interference with the blood supply, and skin wounds closed with interrupted patterns have been shown to have greater tensile strength and less compromise of the microvasculature than those closed with simple continuous sutures. If tension exists across the suture line, the attributes of simple interrupted sutures can be combined with other tension suture patterns.

Simple Continuous Sutures
As with any continuous pattern, knot failure or suture breakage results in breakdown of a large part or all of the incision line. Continuous patterns are quickly placed, but it is not possible to vary the tension on the suture line to the same degree as with an interrupted pattern. Continuous patterns have been shown to result in increased edema and compromised circulation, and to have a prolonging effect on the inflammatory phase of wound healing. Although a simple continuous pattern has some advantages, the lack of precise skin apposition probably makes it inappropriate for use in plastic or reconstructive procedures.

Corner Suture
Also called a three-point or half-buried mattress suture, the corner suture is used to secure the sharp intersecting point of a Y-shaped incision (Fig. 24-2). The intersecting apex of a Y-incision is predisposed to ischemia, and the design of this suture pattern is such that it will not further compromise the blood flow. The three-point suture can also be used in other situations in which a piece of skin has a similar acute angle that is in danger of being underperfused. The corner suture pattern begins like a routine horizontal mattress suture, but instead of penetrating the full thickness, only a partial-thickness bite is taken. The suture is then passed horizontally through the dermis at the point of the V and completed as it was started with a partial-thickness bite.

Tension Sutures
Tension along suture lines can result from attempting to close wounds where there has been loss of skin, swelling in the area, or loss of elasticity in the surrounding tissue of more chronic wounds. Closing wounds under tension should always be performed with caution, but the relationship between the tension on sutures and the incidence of necrosis of skin flaps has been challenged in a study that concluded the vascular damage resulted primarily from the process of undermining the tissue, and that skin with a good
blood supply could be closed under considerable tension without fear of necrosis. Careful judgment is required when increasing stress on suture lines; however, clinical experience suggests that equine wounds can be closed under a reasonable amount of tension and, provided there is a good blood supply and the suture line is well supported by bandages, healing is not delayed. If the force required on individual sutures to appose the skin edges increases to the point where vascular compromise is becoming a threat, tension sutures can be used to minimize the risk. Tension sutures can be used either alone or in combination with appositional patterns such as simple interrupted sutures.

**Mattress Sutures**

Mattress sutures are described as vertical or horizontal, depending on their orientation to the skin edge. These patterns can be used when there is mild-to-moderate tension, and both provide reasonable apposition but have a tendency to evert the skin edges. The vertical pattern is stronger under tension than the horizontal pattern and, as with a simple interrupted suture, results in little if any compromise to the microcirculation. The configuration of the horizontal pattern is such that, if ischemic necrosis results from tissue strangulation, all the tissue within the loop of the suture will be lost, which may compromise subsequent efforts to reconstruct the defect. Mattress sutures can be used together with simple interrupted sutures, and buttons, tubing (rubber, plastic), or gauze can be incorporated into mattress sutures to form a quilled or stented suture to further disperse the pressure forces on the skin. Although quilled sutures are particularly useful on the body where pressure bandages cannot be used to support the suture line, they should be avoided if pressure wraps or casts are to be used.

The corium vertical mattress pattern results in minimal trauma (Fig. 24-3). The suture penetrates the skin and exits at the wound level through the corium (dermis). On the opposite side of the skin defect to be closed, the suture is placed entirely in the corium, where it exits intradermally at the skin edges, penetrates the dermis again at the other side of the defect, and exits near the initial penetrating suture, where the knot is tied. This results in a cosmetically superior closure because the sutures exit on only one side of the defect, which ensures perfect alignment of the skin edges without inversion or eversion.

**Far-Near-Near-Far Suture**

The far-near-near-far suture pattern (or its modified form, the near-far-far-near pattern) combines a tension suture, the far portion, and an appositional suture, the near portion, with the name denoting the order and relative distance the sequential suture bites are taken from the skin edge (Fig. 24-4). This pattern has a higher tensile strength than either a simple interrupted or a mattress pattern, but it has the disadvantage of requiring that a large amount of suture material be placed in the wound.
**Walking Suture**

Walking sutures have been described for closing skin defects in small animals, particularly in areas where the skin fits loosely, such as the trunk. For additional information on this technique see Chapter 17.

**Support for Suture Lines**

Supplying adequate support for sutured wounds can make the difference between success and failure in reconstructive procedures. The method of choice is determined to some extent by the location of the lesion and the amount of tension on the suture line. In many areas, bandages may be used to support a suture line, immobilize adjacent skin and joints, minimize edema formation, and obliterate dead space. Pressure bandages are frequently used to support suture lines; however, a subtle balance exists between providing adequate support of the suture line and causing interference with regional blood flow. As a result of absorption of moisture and compression of the material, pressure bandages constructed from cotton or linen materials soon lose their compressive effect and hence their support. To maintain effectiveness, it is necessary either to change these bandages at frequent intervals or to apply tension with an elastic bandage. A more in-depth discussion on this topic can be found in Chapter 18.

When dealing with repairs on the upper limb or body, the clinician is often limited to the use of stent bandages (tie-over bandages). Stent bandages can provide effective support of suture lines, but they are less effective in preventing or minimizing edema formation. Careful monitoring of these sites is important.

**COSMETIC CLOSURE OF SKIN DEFECTS OF VARIOUS SHAPES**

When undertaking scar revisions or the closure of traumatic wounds, the size of the lesion, the amount of redundant skin in the area, the elasticity of the surrounding skin, and the inherent lines of extensibility are all factors that must be considered during the planning process, and sound clinical judgment remains the cornerstone of making the required surgical decisions. Complex mathematical analyses have been developed to assess the optimal closure patterns of wounds with complex shapes, and these analyses may provide helpful information in the future. The amount of skin that can be excised, the extent of undermining of the surrounding skin, the type of tension-relieving techniques used, the type of suture patterns to be applied, and post-operative support of the repair are other details that should be carefully contemplated when reconstructive or skin mobilization procedures are undertaken.

**Fusiform Defects**

Fusiform defects have sometimes been incorrectly referred to as elliptical defects; the latter do not have the tapered or spindle-shaped appearance of a fusiform excision and do not close as well. Fusiform excisions can be used for elective scar revision, with the long axis of the defect being oriented parallel to the lines of skin tension. A 3:1 or 4:1 length-to-width ratio will allow closure of the defect with a fairly even distribution of tension along the length of the suture line. Shorter, broader defects result in uneven tension and in the formation of dog-ears at the end of the suture line. In fusiform incisions, dog ears can be prevented by tapering the ends of the excised portion of skin. Dog-ears may flatten out over time, but there are methods to surgically manage these irregularities (described later). As with any reconstructive procedure, careful marking of the proposed incision facilitates excision of a piece of skin that has the optimal orientation and length-to-width ratio.

**Triangular, Square, and Rectangular Defects**

Where sufficient movable skin is present to permit closure, triangular defects should be closed from the points of the triangle toward the center, which will result in the formation of a Y-shaped suture line. There is a tendency for the skin at the center of the Y to develop ischemic necrosis. A half-buried horizontal mattress suture in a three-point closure (see Fig. 24-2) can be used to secure this central point with minimal interference with the blood supply.

Square and rectangular defects can also be closed by beginning to suture at the corners of the defect and closing toward the center.

**V-Shaped Defects**

V-shaped defects are fairly commonly encountered in veterinary medicine, and often part of the V-flap is lost or requires debridement prior to closure. After debridement, the resulting chevron-shaped defect can be closed with a Y-pattern in a similar fashion as that described for triangular defects. If the chevron-shaped defect is long and narrow, there is sufficient movable skin in the surrounding area, but a fusiform incision could be made around it, which is then closed like a linear defect.

**Circular Defects**

Closure of circular defects commonly results in the formation of dog-ears, and several techniques have been described to prevent their occurrence. It is possible to close the defect without modifying its circular appearance by orienting the suture line along the relaxed skin lines of tension, followed by removal of any dog-ear as described later. A circle can be converted into either an X- or a Y-shape by tightening sutures placed at three or four points equidistant to each other around the circumference of the defect. The closure can then be completed, although this method also results in the formation of dog-ears.

The simplest method of facilitating closure of a circular defect is to excise two triangles on opposite sides of the circle, thereby creating a fusiform defect. From a geometric point of view, the height of each triangle should be at least equal to the diameter of the circle; this will result in the removal of normal skin equivalent to 1.5 times the area of the original defect. The implications of removing this amount of normal skin must be carefully evaluated.

The double S-shaped incision with a bi-winged excision, the bow tie, and the combined V-incision are alternative methods of modifying circular defects that have been well described. These methods are all designed to minimize...
scarring and dog-ear formation in human cosmetic surgery and are best applied to small circular defects.

Management of Skin Puckers (Dog-Ears)

Skin puckers or dog-ears often develop at the end of the suture line when closing oval or irregularly shaped defects or when using skin flaps as part of a reconstructive procedure. These dog-ears, if ignored, will flatten out to some extent over time and may be of little consequence. If the pucker is small and the cosmetic appearance of limited importance, they can be managed by placing small sutures through half the thickness of the skin. In some locations, however, this conservative approach may result in an unsightly blemish. Because correction of dog-ears requires lengthening of the incision, it is worthwhile to assess the extent to which the cosmetic result will be compromised if the pucker is left alone.

To remove the puckered skin, the dog-ear can be stabilized with an appropriate instrument and removed by incising around the base, which results in a lengthening of the incision line (Fig. 24-5, A). An alternative method is to close the incision until the dog-ear becomes well defined, and then to extend the initial incision through the middle of the dog-ear. This converts the pucker into two small triangular flaps of skin (Burow's triangles), which can be excised at their base (see Fig. 24-5, B).

TENSION-RELIEVING AND SKIN-MOBILIZATION PROCEDURES

Tension on suture lines can result in discomfort for the animal, increased scarring, ischemia of the skin margin, and suture line breakdown with partial or complete wound dehiscence. Allowing for some species variation in the amount of redundant skin, the hair coverage, the vascular supply, and tension on skin, suture lines present less of a problem in animals than in humans. Because of these basic differences, skin wounds in dogs can be closed under moderate tension without deleterious effects provided there is an adequate blood supply to the area. The effect of suture line tension is also influenced by the anatomic location of the lesion. On the lower limb, where there is essentially no redundant skin, excessive tension on suture lines may create a tourniquet effect around the limb, leading to vascular compromise.

The consequences of tension across suture lines can be attenuated by undermining the surrounding skin, by using tension sutures, or by using tension-relieving incisions or skin-mobilization techniques. These techniques may be used alone or in combination.

Surgical procedures in plastic and reconstructive surgery can vary from simple tension-relieving incisions to complex, vascularized, free tissue transplants. Although skin wounds should be closed using the simplest possible technique, despite the paucity of redundant skin, the use of skin-advancement techniques or skin flaps to cover defects is often overlooked by equine practitioners. By successfully using skin-mobilization techniques, the potentially deleterious effects associated with contraction and epithelialization can be overcome; these include excessive scarring, fragile epithelial coverage, and impaired function. Early wound coverage results in a reduced healing time and a more rapid return to function.

Although many of the reconstructive techniques that have been described for both humans and small animals have obvious practical limitations in horses, certain techniques are applicable.

Undermining Skin

Simple undermining can be used alone or in conjunction with other reconstructive procedures, and it is a time-honored method of reducing tension on a suture line when closing a skin defect. As with any surgical procedure, the skin should be handled as gently as possible, with every effort being made to protect the integrity of the blood supply and health of the tissue. Undermining the skin entails separating it from its underlying subcutaneous attachments by dissecting along fascial planes.

Skin can be undermined through either sharp or blunt dissection using scissors or a scalpel (Fig. 24-6). Opening the blades of scissors that have been inserted closed into fascial planes or using the handle of a scalpel in a back-and-forth motion are both accepted methods for bluntly
undermining skin. Blunt dissection has the advantage of minimizing damage to the blood vessels in the area. In chronic, fibrotic wounds, blunt dissection may be difficult to perform, making it necessary to use careful sharp dissection with either a scalpel or scissors; this, however, results in the severance of small subcutaneous blood vessels, increasing both the amount of intraoperative hemorrhage and the chances of hematoma formation after closure. Hematomas have several detrimental effects. They may increase the tension on the suture line, they provide an excellent medium for bacterial growth, and they can interfere with revascularization of transferred flaps. If clinical assessment indicates the possibility of subcutaneous hematoma formation, the surgeon should consider preventive measures such as the use of drains or carefully applied pressure bandages.

The depth at which skin is undermined depends on the vascular supply to the skin and the presence of superficial nerves in the particular area. To prevent damage to these structures, the regional anatomy should be reviewed. Skin on the trunk should be elevated below the level of the panniculus muscle to preserve the small direct cutaneous vessels. On the distal limbs, where no panniculus muscle exists, the dissection plane should be as deep as possible between the subcutaneous tissue and the deep fascia.

Fascial planes are quite easy to identify where an elective incision has been made and primary closure is being used. In older wounds, however, because of scar tissue that develops as a result of the inflammatory process, these planes are not as readily identified until the dissection has been continued some distance from the skin edge. In these situations, it seems appropriate, from a clinical perspective, to begin the dissection at a level that approximates the original thickness of the skin.

The degree to which skin needs to be undermined can be estimated by drawing the skin edges together with towel forces. As a rule, in a fresh wound, a distance equal to the width of the defect itself should be elevated on each side of the wound. If this is not sufficient, undermining can be extended half as much again. Given the potential to disrupt cutaneous blood supply, the cost-to-benefit ratio of expanding the area of undermining requires careful clinical judgment. The extent to which skin can be undermined without significantly damaging the blood supply and causing necrosis has not been objectively studied in either small animals or horses. In small animals, it is thought that undermining can be quite extensive without causing necrosis, provided there is limited interference with the blood supply. Clinical experience suggests the same is true for horses. Used in conjunction with a mesh-expansion technique to repair large defects on the limbs of dogs, 360-degree undermining was not associated with any major complications.

The benefits derived from undermining skin are the result of freeing the skin from its underlying subcutaneous attachments, which allows the surrounding skin to be drawn toward the defect and makes use of the elastic properties of the surrounding skin. The baseline closing tension on standard-size wounds varies significantly in different locations and is related to the amount of loose-fitting skin in the area. Studies in pigs have shown an incremental decrease in wound closure tension associated with increasing the extent of undermining, but the benefits diminished as the extent of the undermining increased.

The physical properties of skin vary at different sites on the body, and thus the benefits of undermining are affected by the location of the wound and any other factors that alter the biomechanical properties of skin. In chronic wounds, as the process of wound healing proceeds, first the inflammatory edema and later the development of fibrous tissue will both lead to a loss of skin elasticity, which may necessitate undermining the adjacent skin more extensively to achieve the desired effect. Having an appreciation of the concept of lines of maximal tension and extensibility in different regions of the body will allow the surgeon to take full advantage of the gains made by undermining.

**Tension-Release Incisions**

A tension-release incision may be thought of as a bipedicle advancement flap, which is described in more detail later. This technique is used to allow the movement of a limited amount of skin in those areas where simple undermining alone does not result in adequate tension relief, yet the size of the defect to be closed does not justify the use of more elaborate procedures. The secondary defect created by the relief incision should be closed, but when planning relief incisions, efforts should be made to create the secondary defect over healthy tissue, thereby minimizing problems associated with second-intention healing should closure not be feasible.
Mesh Expansion

A combination of tension-relieving incisions, mesh expansion, and tissue mobilization has been used successfully to facilitate primary, delayed primary, or secondary closure of wounds in a variety of locations. When compared with open treatment of wounds in horses, the mesh expansion method has been shown, in both experimental and clinical cases, to facilitate closure, to greatly reduce the overall healing time, and to markedly improve the end result.

This technique has the advantage of increasing the percentage of the wound that is eventually covered by full-thickness skin, thus providing a better cosmetic and functional result. Technically, the procedure is simple, does not require any special instruments, and could be performed in most general practices, provided anesthetic facilities are available.

After the surrounding skin is undermined, small stab incisions are made in the undermined skin to permit expansion of this tissue, as is done for a meshed skin graft. The stab incisions are made in staggered rows parallel to the wound edge (Fig. 24-7). Applying traction to the skin edges provides a good indication for the optimal location and orientation of the stab incisions to gain maximal relief of tension. As a guideline, in fresh wounds, the distance between the individual stab incisions and between the adjacent rows should measure approximately 1 cm.

Placing either the rows or the incisions too closely should be avoided so as to prevent the possibility of the adjacent stab incisions becoming confluent or causing focal vascular compromise. The appropriate length of the stab incisions varies depending on the degree of elasticity and pliability of the undermined skin. In fresh wounds, more expansion can be obtained with smaller incisions, whereas for those wounds where the surrounding skin is thickened and fibrotic, longer incisions are required to achieve the same result.

In some older wounds, the stab incisions do not readily open at the time of suturing, but clinical experience has shown that expansion does occur within a few hours postoperatively as a result of the viscoelastic nature of skin. Stress relaxation results in the undermined skin’s becoming fatigued over time and in the stab incision’s opening, which together result in reduced tension on the suture line.

When this technique is used in conjunction with delayed closure in clinical cases, careful excision of excessive granulation tissue from the wound bed to a level slightly below the skin surface has been beneficial. Excising granulation tissue does result in some hemorrhage, which can be controlled by pressure. Hematoma formation is seldom a problem because the presence of the stab incisions allows drainage. A simple interrupted suture pattern, a far-near-far tension suture, or a combination of the two is the preferred method of skin closure.

Postoperative support of the closure is extremely important and, depending on the location of the repair, strong consideration should be given to the use of cast immobilization for 10 to 14 days. Experimental evidence revealed that the use of padded cast bandages did not provide the required support. This was assumed to be caused by compression of the padding, and therefore; if padded bandages are used, they should be changed daily.

As mentioned, wounds on the limbs of horses are often not suited to the use of rotating skin flaps, but the mesh expansion technique has been used on these wounds and to wounds on the head with a very good cosmetic and functional result.

V-to-Y-Plasty and Y-to-V-Plasty

The V-to-Y-plasty technique for relieving tension requires a V-shaped incision with the point of the V directed away from the defect to be closed. Once closure of the original defect has been accomplished, closure of the V incision is done by converting it to a Y (Fig. 24-8). The longer the legs of the V, the greater will be the degree of tension relief; however, this method provides only a limited amount of skin movement. This technique has been advocated for scar revision of the eyelid (see Chapter 56) and for relieving tension when closing elliptical defects. It is less useful for management of large defects.

Conversely the Y-to-V-plasty may be used if additional tension is required, as in the surgical correction of an entropion.

Z-Plasty

Z-plasties can be used to relieve tension along a linear scar, to change the orientation of an incision line or a scar, or to relieve tension when closing a large defect. These effects are achieved by recruiting loose tissue from the sides of the surgical site, and the success of the procedure depends on the presence of sufficient loose skin in the area to permit mobilization of tissue. If this situation does not exist, as in the lower limb of the horse, other procedures may be more suitable.
A Z-plasty represents a modification of a transposition flap. The basic Z-plasty is performed by making a Z-shaped incision with subsequent undermining and transposition of the two triangular portions of skin formed by the dissection (Fig. 24-9). This technique results in a change in the orientation of the central limb of the Z and a gain in its length. The gain in length achieved by this procedure is in the direction of the original central limb—that is, before transposition occurs. Commonly, the Z is symmetric, with the three limbs of equal length and the same angle between the two arms and the central limb. An angle of 60 degrees is most frequently used, which results in a 75% gain in length. Varying the angles of the Z and the length of the arms influences the amount of elongation, and decreasing the angles results in a decreased gain in length. Maintaining a 60-degree angle and lengthening the limbs of the Z can achieve an increased gain in length; however, the greater the increase in length, the greater will be the resultant tension in the surrounding tissue. Using multiple small Z-plasties in the place of a single large procedure can minimize this problem. Although the biomechanics and mathematics of Z-plasties have been examined extensively, this has been done using laboratory models, which are not influenced by the same forces as those found in living tissue.

When Z-plasties are used to realign scars in humans, the limbs of the Z are oriented to follow the lines of minimal tension in the area, and the angles between the limbs of the Z vary according to the obliquity of the scar in relation to the lines of tension. If the procedure is to be used successfully for scar revision in horses, more information on the lines of tension and extensibility in the equine integument is needed.

In the horse, Z-plasties have been recommended as a relaxation procedure for closing elliptical defects and for revision of scars involving the eyelids that have resulted in an acquired entropion. Although other uses undoubtedly exist, the procedure does have some limitations and potential complications. The most common complication encountered with the use of a Z-plasty is ischemia and necrosis of the tips of the triangular skin flaps. The risk of this problem occurring can be reduced by making the base of the flap as broad as possible, and by minimizing tension on the suture line.

**W-Plasty**

W-plasties are designed to improve the cosmetic appearance of a scar. Scars that are at right angles to lines of maximal tension tend, over time, to widen and become cosmetically less acceptable. By using a W-plasty, such a scar is excised by making a series of opposing zigzag incisions in such a way that, when sutured, the incisions will interdigitate, with the result that the final suture line resembles a series of Ws. In using this technique, the orientation of the single scar is changed from being at right angles to the lines of maximal tension, to a series of connected smaller scars that are better aligned with the force of maximal tension and are thus not inclined to widen. Because this procedure involves the removal of tissue, with a subsequent increase in tension on
the surrounding skin, and because it is primarily aimed at cosmetic improvement, careful consideration should be given to the need to undertake the surgery in the first place. If the technique is to be used, a template should be fashioned and the incision lines drawn carefully on the skin to ensure that the two opposing incisions are adequately aligned.

**SKIN FLAPS**

A skin flap or pedicle graft is a portion (or flap) of skin that, once created, can be moved from its original location to a second location on the body while, by virtue of its attachment (or pedicle), it maintains its vascular supply. The survival of these grafts, unlike that of free skin grafts, is not dependent on successful revascularization from the recipient site. Because they are fully vascularized, pedicle grafts can be used to cover areas that, because of an inadequate blood supply, would be unsuitable for free skin grafts. When successful, pedicle grafts reduce healing time, minimize wound contraction and epitelization, and provide a more acceptable cosmetic result with better-quality skin coverage and more hair growth. In contemplating the use of a skin flap, the clinician should evaluate the amount of loose skin in the area. It is preferable to be able to close the secondary defect that is created when the flap is raised, so sufficient skin must be available to be moved without producing excessive tension, either on the donor site or on the suture line at the new location. For this reason, large wounds on the distal limb may not be suitable candidates for a local skin flap, although some success with the use of both advancement flaps and rotating flaps has been reported in treating wounds on the dorsal aspect of the tarsus and in the area of the metacarpophalangeal joint. Pinching the adjacent skin into folds or pushing it toward the center of the primary defect can be used to assess availability of surrounding skin.

Flaps can be classified as local or distant, depending on the relationship of the donor site to the recipient site. Distant flaps usually involve either multiple surgical procedures or a degree of postoperative immobilization and patient compliance that makes them impractical in equine surgery. Local flaps (including rotation flaps, transposition flaps and interpolating flaps) are usually one-stage procedures and can be simple advancement or rotating flaps. These types of flaps have been used successfully in the horse (discussed in more detail later).

Skin flaps can also be categorized as random or axial pattern flaps according to the nature of their vascular supply. Random pattern flaps, which do not have a defined vascular pattern, depend on the subdermal plexus for their survival and have been referred to as subdermal plexus flaps. Axial pattern flaps, on the other hand, contain at least one major direct afferent and efferent cutaneous vessel and are usually named in accordance with that vessel. In the dog, the omocervical, thoracodorsal, and caudal superficial epigastric flaps are well recognized and established axial pattern flaps. In horses, local random pattern flaps have greater potential use than axial pattern flaps.

Flap survival depends on the survival of its intrinsic vasculature. Random pattern flaps have traditionally been defined by the length-to-width ratio. Although the detailed differences in regional blood supply to the skin have not been studied in the horse, differences have been reported in other species, and several studies have shown that the optimal ratio for a flap varies with the location on the body. Length-to-width ratios from 1:1 to 3:1 for single-pedicle and 1.5:1 to 3:1 for bipedicle flaps have been reported in the veterinary literature. However, studies in dogs and pigs have shown that flaps of a standard length with similar vascularity survive regardless of the flap width. In horses, a correlation of flap width to viable length in random-pattern pedicle flaps of the trunk has been shown. Length-to-width ratios of 1.5:1 and 3:1 have been used successfully on the limb and head, respectively. The narrower the pedicle of the flap, the more maneuverable it will be, but the greater will be the chances of compromising its blood supply. On the other hand, a wide-based flap will have a good vascularity, but mobility, particularly rotational, is limited.

The delay phenomenon has been used to enhance the blood supply to the skin to increase the chances of flap survival. This two-stage procedure involves incising and undermining the skin and subcutaneous tissue of the proposed flap and then leaving it sutured in its original location for a period of time. The incision may be on three adjacent sides of the flap or on two opposite sides, and undermining may extend to involve all or part of the flap. The most appropriate period of delay varies between species: in rabbits and pigs, 8 to 10 days is adequate, whereas circulation in single-pedicle flaps in dogs rose to 150% of normal in 3 weeks. Although the mechanism by which flap survival improves using this technique is not well understood, both denervation and ischemia have been shown to play a role. Both contribute, with a resultant increase in the number and diameter of the vessels as well as an increase in blood flow into the flap through its primary attachments. Although this technique is not commonly used in equine reconstructive surgery, as the horizons of plastic surgery in the horse are advanced, specific studies are required to determine the most appropriate method and optimal time delay.

Tension applied to pedicle grafts has been shown to decrease blood supply and thus increase flap necrosis in pigs. However, a study assessing the effect of tension on perfusion of axial and random pattern flaps in foals concluded that adequate perfusion was maintained in equine axial pattern flaps even when subjected to high tension. Assessment of flap viability based on clinical criteria, such as temperature and color, is probably adequate. Other, more sophisticated techniques, such as radioisotope tests, histamine wheal, and fluorescein tests, have been described but are not routinely used. It is debatable whether venous compromise or arterial compromise, or a combination of both, is of prime importance in flap necrosis; however, tension on the pedicle from stretching or over-rotating should be avoided to help prevent flap necrosis. Several methods for improving flap survival, in addition to the delay phenomenon, have been suggested; these include the use of vasodilators, massage, dimethyl sulfoxide, and hyperbaric oxygen, but all are of questionable clinical value and require further investigation before they can be recommended. Attention to the specific anatomy of local cutaneous vasculature is important in flap elevation. Flaps raised on the trunk should be elevated beneath the cutaneous musculature, whereas on the limb, dissection should be performed deep in the subcutaneous tissue. Careful design of the flap

RECONSTRUCTIVE AND PLASTIC SURGERY 265
and good postoperative care greatly improve the success rate achieved. Planning should include determining which type of skin flap is to be used as well as mapping and marking the borders of the piece of skin to be elevated. This can be done using a paper towel or a cloth template of the defect to be covered. The flap should be slightly larger than the defect. Sharp corners, which may be prone to ischemia, should be avoided.

Advancement Flaps

Advancement flaps are random pattern flaps that can be of either the single or the bipedicle type. They have also been referred to as sliding flaps because there is no rotation of the elevated skin. A V-Y-plasty is an example of an advancement flap.

Simple bipedicle advancement flaps are performed either by making a single longitudinal incision on one side of the wound or by incising on each side of the defect. These incisions are made parallel to the wound edge to create skin flaps that are approximately the same width as the original defect. The bipedicle nature of this flap (Fig. 24-10) provides two sources of blood supply to ensure survival of the mobilized portion of skin. The flaps and surrounding skin can be undermined and the initial defect closed. Depending on the nature of the surrounding skin, the new defects can be either closed or left to heal by contraction and epithelialization. As with many types of flaps, moving a single or bipedicle advancement flap may create some laxity in the adjacent skin. This can be managed by removing small triangular portions of skin called Burow’s triangles, thereby preventing the formation of a dog-ear at the end of the suture line.

An H-plasty is a modification of a single-pedicle flap and is used to mobilize tissue during closure of a rectangular defect. Two single-pedicle flaps are used on opposite sides of the defect to advance the skin, and Burow’s triangles are excised at the base of both pedicles to avoid dog-ear formation (Fig. 24-11).

Rotating Flaps

Rotating flaps can be one of three types: rotation, transposition, or interpolating flap. A rotation flap requires making a semicircular incision and moving the tissue laterally to cover the defect (Fig. 24-12). A rectangular, single-pedicle flap that is created adjacent to a defect and subsequently rotated on its pedicle is called a transposition flap (Fig. 24-13). These can be rotated up to 180 degrees, but increasing the amount of rotation has the effect of shortening the flap, which must be considered when planning the surgery. Moving a similar rectangular flap onto an immediately adjacent defect (i.e., the pedicle bridges an intact portion of the skin) creates an interpolating flap (Fig. 24-14). The successful use of a rotating flap has been described in the management of a lesion on the cranio-lateral aspect of the tarsus of a horse.

Vascularized Free Tissue Transfers

Vascularized free tissue transfers, based on axial pattern flaps and using microvascular surgical techniques, have gained popularity and are now commonly used in many small animal surgical practices. Attempts have been made to adapt this technology for use in repairing skin defects in horses. In the horse, a large axial pattern flap has been described using the deep circumflex iliac artery and vein, and a smaller one is based on the saphenous artery and the medial saphenous...
Attempts to use these flaps to cover distant defects in experimental models have been unsuccessful. In two separate studies, none of the heterotopically transferred flaps survived for longer than 4 to 6 days. The reasons for failure are not fully understood but may include poor perfusion as a result of vasospasm, a species tendency toward vascular thrombosis, or ischemia-reperfusion (IR) injury. Neutrophils are a significant source of the oxygen free radicals that mediate IR injury. A study to assess the role that IR injury plays in the failure of vascularized free tissue transfer in the horses showed no difference in neutrophil accumulation between control myocutaneous flaps and those subjected to a period of ischemia and reperfusion. Although the initial results are disappointing, further studies may resolve the difficulties encountered and make this technique a viable option in the future.

INDICATIONS FOR GRAFTING

The most common indication for applying a skin graft to a horse is a wound so large that it cannot heal by any other means, but the presence of any open wound that cannot be sutured is an invitation for grafting (Fig. 25-1). The rapid healing achieved with a skin graft may make grafting the most economical choice for managing some wounds that cannot be sutured. A healed skin graft contains some epidermis, dermis, and some adnexa, including hair follicles, so it is likely to be more cosmetic and resilient than a wound healed primarily by epithelialization. Skin grafting should not be regarded as an option of last resort and should not be avoided because of fear of failure. Many techniques of skin grafting require little experience and only basic surgical equipment.

GRAFT CLASSIFICATION

The two basic types of skin grafts are the pedicle graft and the free graft.1-3 A pedicle graft remains connected to the donor site, at least temporarily, by a vascular pedicle that sustains the graft, ensuring its viability. A pedicle graft is useful for covering a poorly vascularized wound, because the graft does not depend on the vascularity of the recipient site. The cosmetic appearance of wounds healed by application of a pedicle graft is good, because all components of skin are transferred. Cutaneous wounds of horses are rarely covered with a pedicle graft because the inelastic nature of equine skin makes mobilizing an adequate amount of skin for advancement difficult.4 In humans and dogs, skin flaps that incorporate a direct cutaneous artery and vein (i.e., axial-pattern flaps) can be transferred to adjacent sites, or even to remote sites, by using microsurgical techniques to anastomose the flap’s vessels to local recipient vessels.5 Similar transfers in horses are unsuccessful, apparently because of reperfusion injury to the graft.6,7

A free skin graft is a piece of skin that has been completely separated from its local blood supply and transferred to a wound at another site, where it must establish new vascular connections to survive.8,9 Free grafts can be categorized in several different ways, one of which is by their source. Most skin grafts applied to wounds of horses are autografts (or isografts), which are grafts transferred from one site to another on the same individual10 (Table 25-1). The recipient of an autograft mounts no detrimental immune response against the graft because the recipient and donor are one and the same. Autografting is the most common and practical type of grafting of wounds of horses.

A graft transferred between different members of the same species is an allograft (or homograft), and a graft transferred from one species to another is a xenograft (or heterograft). The recipient of an allograft or xenograft mounts an immune response against the graft, causing the graft to be eventually rejected.8,11 A second allograft from the same donor applied to the wound survives only a few days, but an allograft from a different donor survives for about the same time as the first allograft.8 Because the immune mechanism is highly specific, an allograft from a different donor is not affected by circulating lymphocytes sensitized against the first allograft. Although allografts and xenografts are rarely applied to wounds of horses, these grafts are occasionally useful as a biologic bandage.12-14

Free skin grafts can be categorized according to their thickness. Full-thickness grafts are composed of epidermis

and the entire dermis; split-thickness (or partial-thickness) grafts are composed of epidermis and only a portion of the dermis. The percentage of dermis within the graft influences the graft’s acceptance, durability, and cosmesis at the recipient site. The thickness of dermis within the graft is directly proportional to the graft’s durability and cosmesis but inversely proportional to the ability of the graft to survive.

Full- or split-thickness free skin grafts can be applied to the surface of wounds as solid or meshed sheets, or they can be embedded in granulation tissue as pinch, punch, or tunnel grafts. Each method of free grafting has its merits and drawbacks, and the method selected depends on circumstances, such as the size and location of the wound, the necessity for cosmesis, the financial constraints imposed by the owner, the equipment available, and the expertise of the surgeon.

**PHYSIOLOGY OF GRAFT ACCEPTANCE**

**Recipient Bed Characteristics**

A prime requisite for free grafting is a recipient bed that is vascular and free of infection and devitalized tissue. A free graft cannot be expected to survive if placed on bone denuded of periosteum, tendon denuded of paratenon, or cartilage denuded of perichondrium, but practically any other tissue is capable of supporting a free graft. Fresh, surgically created wounds or fresh, clean wounds caused by accident are vascular and free of infection and so readily accept a graft. Granulating tissue is also capable of accepting a graft, although not as readily as is fresh tissue. Granulation tissue healthy enough to allow epithelium to proliferate at its margin is generally healthy enough to accept a skin graft (Fig. 25-2).

**Adherence**

The graft is initially adhered to the recipient site by fibrin, which binds to collagen within the graft. Vessels and fibroblasts invade the fibrin matrix by the 4th or 5th day, and the graft becomes firmly united to the recipient bed by around the 10th day.

**Serum Imbibition (Plasmatic Circulation)**

The newly applied graft is nourished by plasma-like fluid that it passively imbibes, by capillary action, into its open vessels, a process referred to as plasmatic imbibition or plasmatic circulation. Oscillating movement of fluid into the vessels keeps the vessels open for revascularization. The graft becomes edematous and remains so until vascular connections to the graft are restored.

**Revascularization**

After about 48 hours, new capillaries generated in the recipient bed traverse the fibrin layer to anastomose with those in the graft, a process called inosculation. Simultaneously, new capillaries from the recipient bed invade pre-existing vessels within the graft, and others cut new vascular channels into the dermis (called neovascularization). The graft revascularizes between the 4th and 5th day after grafting, and reestablishment of circulation and lymphatic drainage brings about resolution of edema.

Vascular bridging is a phenomenon that may enable a portion of the graft overlying a relatively avascular portion of the wound to revascularize. With vascular bridging, capillaries enter the portion of the graft overlying the avascular portion of the wound from the relatively highly vascular aspects of the surrounding recipient bed to create a vascular bridge across the avascular portion of the wound. For vascular bridging to occur, the avascular area of the wound must be small, and the surrounding area must be highly vascular. Full-thickness grafts bridge avascular areas better than split-thickness grafts, because collateral circulation within the dermis of a full-thickness graft is less interrupted than that within the dermis of a split-thickness graft.

**Organization (Organic Union)**

The epidermis of the graft becomes hyperplastic after grafting and can double in thickness during the first 2 weeks. The epidermis, especially that of a full-thickness graft, may die and slough in some areas, exposing pale dermis beneath it (Fig. 25-3). The exposed dermis may closely resemble granulation tissue, so a surgeon may remove the upper layer of the wound in preparation for a second graft, not realizing that a portion of the dermis has been accepted. Dermis can be differentiated from granulation tissue by its paler color. Exposed dermis becomes covered with epithelial cells that migrate from the hair follicles and the eccrine glands within the dermis.

Split-thickness skin grafts of humans usually begin to develop pigment about 4 weeks after grafting, and the same is true of split-thickness grafts of horses. Split-thickness grafts often remain scaly for several months, until the eccrine glands regenerate. Split-thickness grafts of horses, no matter the thickness at which the grafts are harvested, are likely to be devoid of sweat glands, and even full-thickness grafts of horses may be devoid of sweat glands.

Hair begins to appear in split-thickness grafts at
between 4 and 6 weeks\textsuperscript{26} and often grows to a greater than normal length.\textsuperscript{29} Re-innervation returns more rapidly, but to a lesser extent, in split-thickness grafts than in full-thickness grafts.\textsuperscript{17,30} Sensation in split-thickness grafts of humans usually first appears between the 7th and 9th weeks but can occasionally be present as early as the 10th day.\textsuperscript{31} Sensation in split-thickness grafts remains incomplete and patchy. Regional nerves enter the base and margins of the graft and, by following vacated neurilemmal sheaths, reconstruct the innervation pattern of the grafted skin.\textsuperscript{30} Humans sometimes suffer from hyperesthesia of the grafted wound, \textsuperscript{18,30} and this may occur in horses also.

**Graft Contraction**

After being harvested, grafts immediately shrink because of recoil of the elastic fibers within the deep, dermal layers.\textsuperscript{15} This shrinkage is referred to as primary contraction. Primary contraction is greatest in full-thickness grafts and decreases as grafts become thinner. Full-thickness grafts from humans contract to close to half their original size after being harvested. Split-thickness grafts that are about half the thickness of the whole skin contract to about three-quarters of their original size, and grafts composed solely of epidermis do not shrink at all. The consequences of primary contraction are minor, because it is reversed when the graft is stretched and sutured or stapled to the recipient site.

Although grafts appear to contract after being accepted, this contraction is probably caused by contraction of the recipient bed, not by the graft itself.\textsuperscript{15} Open wounds heal, at least in part, by contraction, which is brought about by the action of contractile fibroblasts, or myofibroblasts, within the wound.\textsuperscript{15,32} Skin grafts inhibit wound contraction, to various extents, by accelerating the life cycle of the myofibroblasts within the wound.\textsuperscript{8}

The extent to which a skin graft is capable of inhibiting wound contraction is influenced by the relative thickness of the graft’s dermis and the stage of healing of the recipient bed at the time of grafting.\textsuperscript{15,32,33} The total percentage of the dermis grafted is more important than the absolute thickness of the skin graft in preventing wound contraction. Fresh or granulating wounds of humans and rats receiving a full-thickness graft tend to contract less than wounds receiving a split-thickness graft, even when the full-thickness graft is thinner than a split-thickness graft, indicating that physical or biochemical differences between the upper and lower portions of the dermis may strongly influence the effect of the skin graft on wound contraction.\textsuperscript{15,34}

In a study on the effects of grafts on wound contraction in horses, fresh or granulating wounds to which a split-thickness graft was applied contracted at the same fractional rate as fresh or granulating wounds to which a full-thickness graft was applied.\textsuperscript{35} The fractional rate of contraction of grafted fresh wounds, however, was less than that of grafted, granulating wounds.

Contraction of wounds of humans can sometimes lead to considerable cosmetic defects and to contracture, which is deformity of one or more joints caused by contraction of the wound.\textsuperscript{8} Contraction of wounds of humans is sometimes intentionally inhibited by autografting or allografting to prevent cosmetic and functional defects caused by contraction.\textsuperscript{2} Skin of horses is more mobile than that of humans and so is more capable of healing by contraction. Contraction of wounds of horses rarely, if ever, causes contracture of joints, so contraction of wounds of horses, before or after grafting, should be considered beneficial. If applied to a wound after contraction has commenced, skin grafts, regardless of whether they are full-thickness or split-thickness, appear to have little effect on inhibiting contraction in horses.\textsuperscript{36}

**GRAFT FAILURE**

Reasons for graft failure include fluid accumulation beneath the graft, movement, and infection.\textsuperscript{15,18,22,23,29} Grafts applied to horses fail most frequently because of infection.\textsuperscript{37}

**Fluid Accumulation**

The graft must contact the wound intimately to prevent fluid from becoming interposed between the graft and the wound.\textsuperscript{23} A hematoma, seroma, or exudate beneath the graft prevents fibrin from attaching the graft to the wound and acts as a barrier to the ingrowth of new vessels.\textsuperscript{16,23} A graft can survive for only several days by imbibing nutrients from the hematoma or seroma, and if budding capillaries from the recipient bed are unable to traverse this barrier within this time, the graft expires. To avoid formation of a hematoma or seroma beneath a graft, grafting of a hemorrhagic wound should be delayed until hemorrhage has ceased.

**Infection**

Granulation tissue always has resident bacteria at its surface, but it contains abundant blood vessels and phagocytic cells
that act as a partial barrier to bacterial invasion.* The wound becomes infected when the concentration of bacteria in the tissue exceeds the ability of humoral and cellular defenses to destroy the bacteria, and for most types of bacteria, this concentration seems to be about $10^5$ organisms per gram of tissue. Survival of a skin graft is better correlated to the concentration of bacteria in the recipient bed than to any other single factor.40,41 If a wound is found, by quantitative bacterial analysis, to contain more than $10^5$ bacteria per gram of tissue, the wound should not be grafted.

Because quantifying the concentration of bacteria in a wound is time-consuming and often impractical, at least for most veterinary surgeons, and because the concentration of bacteria in the wound is sometimes not as important as the type of bacteria,22 the bacterial status of a wound to be grafted is usually assessed qualitatively. A wound that shows signs of inflammation, such as redness, swelling of the surrounding area, and formation of exudate, should be assumed to be infected. Bacteriologic culture of a wound that appears to be infected should precede grafting, and isolates should be tested for antimicrobial susceptibility. Unfortunately, even a wound that has no signs of inflammation and appears to be healthy may have more than $10^5$ bacteria per gram of tissue.41

The concentration of some bacteria, most notably β-hemolytic streptococci, required to infect a wound is much less than $10^5$ per gram of tissue.22,38 β-Hemolytic streptococci produce proteolytic enzymes, including streptokinase and staphylokinase, that are destructive to both the graft and its recipient bed. These bacterial enzymes, and others, destabilize the fibrin network between the graft and the recipient wound by catalyzing the conversion of plasminogen to plasmin, which digests fibrin.22,42 Pseudomonas species also critically weaken a graft’s fibrinous attachment by producing elastase, which specifically degrades elastin in the dermis of the graft to which fibrin attaches.22

**Motion**

The graft must remain immobilized long enough to become vascularized. Shearing forces between the graft and the underlying recipient bed dislodge the fibrin seal, impairing plasmatic imbibition, inosculation, and capillary ingrowth. Shearing forces occur when the recipient wound is located in a highly mobile area, such as over a joint, or when the grafted area is inadequately immobilized.

**GRAFTING TECHNIQUES**

**Preparation of the Recipient Site**

Preparation of the recipient site is the most important contributor to survival of a free graft.4 Factors to consider when determining if a wound is prepared sufficiently to accept a graft are the wound’s vascularity and whether the wound appears to be infected.17 Grafting should be delayed if the wound appears to have inadequate vascularity to support a free graft or if it appears to be infected or to have a higher than ordinary vulnerability for developing infection.

Highly vascular granulation tissue readily accepts a graft, but as the granulation tissue matures, its vascularity and ability to accept a graft diminish38 (Fig. 25-4). Fibrous, poorly vascularized granulation tissue, or granulation tissue plagued by unremitting infection, should be excised to a level below the margin of the wound to allow the wound to form fresh, vascular granulation tissue free of infection before a graft is applied.29 Granulation tissue can usually be excised with the horse standing, because granulation tissue has no innervation.

Delaying grafting of a fresh wound for several days may decrease the time required for the graft to revascularize.43 Sprouting capillaries capable of rapidly revascularizing the graft develop in the wound within 48 hours, so, by delaying grafting for 2 days after wounding, the time before the graft begins to revascularize (i.e., the phase of plasmatic imbibition) can be reduced by about one half. Wounds that are allowed several days to develop sprouting capillaries before being grafted are referred to as prepared wounds.

Although eliminating all bacteria from a wound is difficult, removing streptococci is relatively easy, because streptococci are nearly always susceptible to penicillin.38,44,45 Occasionally, penicillin or other β-lactam antibiotics are ineffective in resolving a streptococcal infection, because other resident bacteria, particularly staphylococci and gram-negative bacteria, produce β-lactamase, an enzyme that inactivates β-lactam antibiotics.44 The efficacy of the β-lactam antibiotic against streptococci can be preserved if

---

*References 8, 16, 17, 22, 38, 39.
the β-lactam antibiotic administered is effective against β-lactamase–producing bacteria as well as streptococci. The activity of the β-lactam antibiotics can also be preserved by administering clavulanic acid, a potent inhibitor of β-lactamase, in conjunction with the β-lactam antibiotic.44 Clavulanic acid has no therapeutic value when administered alone. Pseudomonads are usually sensitive to topically applied mafenide acetate, aminoglycosides, or polymyxin-B sulfate.15,46

Topical application of an antimicrobial drug to an infected, granulating wound is often more effective for eliminating infection than is systemic administration of the same antimicrobial drug, because systemically administered antimicrobial drugs often fail to reach therapeutic concentrations within granulation tissue.17,47 Fibrin within granulation tissue appears to prevent adequate penetration of the antimicrobial drug.

Before a wound is grafted, it should be evaluated thoroughly for evidence of damage to synovial structures, ligamentous or tendinous tissue, or bone. Bone beneath slowly healing wounds or beneath wounds with draining tracts should be examined radiographically for evidence of a foreign body and for evidence of infection or sequestration of bone (Fig. 25-5). Granulation tissue within chronic, slowly healing wounds, particularly those wounds that appear to be pruritic, should be examined histologically for the presence of larvae of the equine stomach worm Habronema. Some neoplasms, such as sarcoids or carcinomas, sometimes resemble granulation tissue. Preparation of the recipient bed immediately before grafting should include clipping or shaving the skin around the wound. A surgical scrub solution can be used to cleanse the skin around the wound, but the wound itself should be cleansed by rinsing it with physiologic saline solution or a balanced electrolyte solution. Contact between the wound and the detergent found in surgical scrub solutions increases the wound’s susceptibility to infection.48

Preparation of the Donor Site
The area selected as the donor site depends on the technique of grafting selected, and on whether the graft is to be harvested with the horse anesthetized or standing. Because harvesting skin creates a wound, the donor site, especially the donor site of a split-thickness graft, should be at an inconspicuous location.

Hair is removed from the donor site by clipping with a no. 40 clipper blade, by shaving, or by applying a chemical depilatory agent. Although chemical depilatory agents may irritate the donor skin, they have no clinically apparent detrimental effect on acceptance of grafts (my observation). When hair is removed completely from the surface of the donor site by shaving or by depilation, the graft should be marked in such a way that ensures that when the graft is applied, the direction of its hair growth matches that of the skin surrounding the recipient site. The direction of hair growth on the graft remains visible when the donor site is clipped. After the donor site is scrubbed, it should be rinsed thoroughly with water or physiologic saline solution so that no residue detrimental to the graft, such as isopropyl alcohol, remains.

Full-Thickness Sheet Grafting
The site most suitable for procuring a full-thickness graft is the cranial pectoral region, where the skin is relatively mobile (Fig. 25-6).49,50 The graft can be removed, and the donor site sutured, with the horse anesthetized or with the

Figure 25-5. A graft applied to a healthy-appearing, granulating wound on the dorsal aspect of a metacarpus was completely accepted, but a draining tract soon appeared in the healed wound. Drainage was caused by infection of bone beneath the wound.
horse standing and sedated after desensitizing the donor site with local anesthetic solution. If a sutured wound in this region should dehisce, healing occurs rapidly by contraction with little or no scarring (my observation). The graft should be cut slightly larger than the recipient site, even though the shrinkage caused by recoil of elastic fibers is largely reversed when the graft is stretched and fixed to the margin of the wound.3,15

Subcutaneous tissue attached to the undersurface of the graft acts as a barrier to plasmatic imbibition and ingrowth of new vessels, so it must be removed to expose the dermis and its vasculature.1,3,23 Fascia and fat should be removed by sharp dissection, because scraping the subcutaneous tissue from the graft can injure the dermis and its vasculature (Fig. 25-7). The graft should be attached to the recipient site with slight tension to keep the small dermal vessels open for inosculation.51

Full-thickness sheet grafting requires no sophisticated equipment for harvesting and can be performed with the horse standing. Full-thickness skin grafts resist trauma better than split-thickness skin grafts, and because they contain all the properties of the surrounding skin, full-thickness skin grafts provide the best cosmetic appearance and function of any type of free graft.2,3,8,37,32

Full-thickness grafts are not accepted as readily as split-thickness grafts, because they have fewer exposed blood vessels than split-thickness grafts, and because their requirement for nourishment is greater.2,23,52,53 Circumstances for full-thickness grafting must be ideal, because blood vessels in a full-thickness graft that are available for diffusion of nutrients or for inosculation by vessels in the recipient wound are few in number and large in diameter. Although healthy, highly vascular granulation tissue is capable of accepting a full-thickness skin graft,31 full-thickness grafting is usually reserved for fresh, uncontaminated wounds.2,5,6,17,26,38

A considerable disadvantage of full-thickness grafting of wounds of horses is the horse’s lack of redundant donor skin. This disadvantage makes full-thickness grafting practical for covering only relatively small wounds, provided that the surgeon intends to suture the donor site after the graft is harvested. A full-thickness graft can be used to cover a wound larger than the graft itself by meshing and expanding the graft, but full-thickness skin of horses is too thick to be easily meshed using some commercial meshgraft dermatomes, such as the Zimmer mechanical skin mesher (see “Meshing Sheet Grafts,” later).

**Split-Thickness Sheet Grafting**

A split-thickness graft is composed of epidermis and a portion of the dermis. The thickness of a split-thickness graft is determined by the relative amount, rather than the absolute amount, of dermis included in the graft, because the thickness of the dermis varies between individuals and between regions.2,28,29 To obtain a split-thickness graft, a portion of the dermis with its overlying epidermis is harvested with a free-hand knife, a drum dermatome, or a power-driven dermatome. Relatively inconspicuous donor sites for obtaining a split-thickness graft from horses are the ventral portion of the abdomen and the ventrolateral aspect of the thorax, caudal to the elbow.49,54-56

**Hand Instruments**

Scalpel blades, double edged razor blades, and surgical straight razors are sometimes used to harvest small, split-thickness grafts from humans, but these types of dermatomes are of little use for harvesting skin grafts from horses, because they can be used to harvest only relatively small grafts, and because their use requires considerable technical expertise to obtain a graft of consistent thickness. Large grafts necessary to cover wounds of horses can be cut with a variety of knives designed specifically for harvesting skin. The Watson skin grafting knife (Padgett Instruments, Inc, 1520 Grand, Kansas City, Mo), a modification of the Braithwaite knife, can harvest a graft 100 mm (4 inches) wide, uses disposable blades, and is fitted with an adjustable roller in front of the blade to control the depth of the cut (Fig. 25-8). Because the thickness of the graft is controlled by the adjustable roller, only a moderate amount of practice is required to develop the expertise necessary to achieve a uniform, split-thickness graft of the desired thick-
ness. The position of the adjustable roller is controlled by a screw marked with calibrations at one end and a lock at the other. The thickness of graft represented by each calibration is learned by experience. The thickness of the graft depends not only on the position of the roller but also on the angle of incidence at which the skin is cut, and on the pressure applied to the knife while cutting. The heavier the pressure and the greater the angle of incidence, the thicker is the harvested skin.

**Drum Dermatomes**

A clinician with only minimal training can harvest a uniform section of skin with a drum dermatome. The drum dermatome uses a knife that oscillates back and forth on a piston to precisely split the dermis of a section of skin that has been glued to the drum of the dermatome (Fig. 25-9). The depth of cut is predetermined by the caliber of shims placed next to the blade.

The drum dermatome allows the surgeon to harvest a graft of the exact dimensions to fit the wound for which the graft is intended. Using a template from the recipient site, glue is applied only to a similar area on the drum, so that as the drum is rotated, only that portion of skin that adheres to the drum is cut. The drum dermatome requires no external power source. It is considerably more expensive than a free-hand knife but not as expensive as power-driven dermatomes. A major drawback to the use of the drum dermatome to harvest grafts for wounds of horses is that the length of the graft is limited by the circumference of the drum. An example of a drum dermatome is the Padgett Manual Dermatome (Z-PD-100R, Padgett Instruments, Inc, Kansas City, Mo).

**Power-Driven Dermatomes**

Power-driven dermatomes use a rapidly oscillating blade, driven by an electric motor or gas turbine to harvest a split-thickness skin graft with predictable precision. The depth and width of cut can be adjusted precisely. Commonly used power-driven dermatomes are the Stryker electric dermatome (Stryker Electro-Surgical Unit, Kalamazoo, Mich) and the Brown pneumatic or electric dermatome (Zimmer, Warsaw, Ind) (Fig. 25-10). The cutting head of a pneumatic dermatome oscillates more rapidly than that of an electric dermatome, making harvesting smoother.

The Davol-Simon skin graft dermatome (Davol Inc, Cranston, RI) is a relatively inexpensive dermatome powered by a rechargeable handle, similar to the handle of an electric toothbrush. A disposable, nonadjustable cutting
head harvests a split-thickness skin graft 33 mm (1 1/2 inches) wide and 0.38 mm (0.015 inch) thick. Grafts obtained with this skin graft dermatome are too thin to impart a cosmetic appearance to wounds of horses, but they may be useful for covering relatively small wounds when cosmetic appearance is not important.

Although a power-driven dermatome provides precision harvesting, the widest graft that can be harvested with many power dermatomes is only 76 mm (3 inches). A surface firmer than the ventral aspect of the abdomen, the least conspicuous donor site on the horse, is often necessary when harvesting with a power-driven dermatome. Although operating a power-driven dermatome requires only a minimum of experience, a power-driven dermatome requires skilled maintenance. Because of their expense, power-driven dermatomes are found primarily only at large equine surgical referral centers.

An advantage of the free-hand knife over the power-driven dermatome is that consistently uniform grafts more than 100 mm wide (4 inches or greater) can be harvested using a free-hand knife. Grafts can be harvested from the ventral aspect of the abdomen with a free-hand knife, which is a difficult feat for a power-driven dermatome. A free-hand knife is far less expensive than a power-driven dermatome, requires less maintenance, has fewer parts to malfunction, and is easier to sterilize and to transport.

**Technique of Harvesting a Split-Thickness Graft**

A split-thickness skin graft can be harvested from any convex surface of the body, but the cosmetic appearance of the horse should be considered when selecting a donor site, because a split-thickness graft of acceptable durability and hair-coverage cannot be obtained without creating a large epithelial scar at the donor site. Harvesting a split-thickness skin graft is painful to the horse and can be accomplished only when the horse is anesthetized.

To harvest skin from the ventral aspect of the horse’s abdomen using a free-hand knife, the horse is positioned in lateral recumbency with its abdomen protruding beyond the edge of the table. The ventral portion of the abdomen must protrude over the edge of the table to accommodate the handle of the hand-held knife. The donor site is prepared for aseptic surgery, but draping is not necessary. Harvesting usually begins at the umbilicus and extends cranially. The donor site can be stabilized, if necessary, by assistants stretching the skin with towel clamps. The knife is applied to the skin at an acute angle of about 5 to 10 degrees, and the skin is cut using a regular sawing motion, concentrating on moving the blade back and forth, rather than pushing it forward (Fig. 25-11). Lubricating the donor site with physiologic saline solution and the blade with a light coating of mineral oil reduces friction. Mineral oil does not adversely affect acceptance of the graft. Slight, uniform tension should be applied to the cut end of the graft as the graft is harvested.

After several centimeters of graft have been cut, the graft and donor site should be inspected to ensure that the graft is the desired thickness before harvesting is continued. The thickness of the graft can be assessed subjectively by examining the graft for translucency and the donor site for the pattern of bleeding. A shallow cut through the dermis produces a translucent graft and exposes many small bleeding vessels, whereas a deep cut produces a more opaque graft and exposes fewer but larger bleeding vessels. If subcutaneous fat is exposed, the graft is full-thickness and therefore much too thick. The depth of cut can be changed by repositioning the adjustable roller, by changing the pressure applied to the knife, or by raising or lowering the knife’s angle of incidence. When the desired length of graft has been cut, the knife is tilted upward to sever the graft. If the graft is to be meshed and fully expanded, the length of graft should be considerably longer than the wound to which it is applied, because expanding the graft’s width also shortens the graft’s length.

The split-thickness graft is the most useful type of graft, because it can be used to cover defects too large to be covered by a full-thickness graft, and because it survives more readily than does the full-thickness graft. The cosmetic appearance of a wound healed by split-thickness skin grafting is inferior to that of a wound healed by full-thickness skin grafting, but it is superior to that of a wound healed by island grafting (see “Island Grafts,” later). A split-thickness graft is less conveniently procured than a full-thickness graft, because to obtain a split-thickness graft, the horse must be anesthetized.

**Meshing Sheet Grafts**

A split-thickness or full-thickness sheet graft can be applied to a recipient bed as a solid or as a meshed sheet. A graft is meshed by uniformly fenestrating it manually with a scalpel blade or mechanically with a meshgraft dermatome. The primary reason for meshing a sheet graft is to allow the graft to uniformly cover a wound larger than the graft itself. Grafts are also meshed to prevent serum, blood, or exudate from mechanically disrupting a newly applied graft from its delicate fibrinous and vascular attachments to the recipient

*References 2, 16, 17, 23, 29, 49, 54-59.*
bed. Fenestrations also enable a topically applied antimicrobial agent to contact a large portion of the recipient wound. A meshed graft conforms to an irregular surface better than does a nonmeshed graft, and its ability to expand allows it to better tolerate motion. Fenestrations in the graft fill with fibrin, which increases the graft’s stability on the recipient bed.

An example of a mesh graft dermatome is the Padgett mechanical skin mesher (Mesh Skin Graft Expander, No. Z-PD-170, Padgett Instruments, Kansas City, Mo). This instrument consists of an aluminum block with staggered, parallel rows of blades and a Teflon rolling pin. The graft is positioned on the block, dermal side down, and pressed into the cutting blades, in the direction of the blades, with the rolling pin (Fig. 25-12). The rolling pin should first be rolled lightly across the graft to secure the graft to the blades of the mesher and then firmly so that the blades pierce the graft. The staggered cuts produce a meshed pattern that allows the graft to be expanded to three times its original width.

An important consideration when purchasing a mesh graft dermatome is the width of grafts routinely harvested with the skin graft dermatome. Grafts up to 100 mm wide are harvested routinely with a free-hand skin graft knife, but a graft wider than 76 mm is difficult to mesh with a Zimmer mechanical skin mesher. Grafts up to about 110 mm wide can be fitted onto the cutting surface of the Padgett mechanical skin mesher. Although the Padgett mechanical skin mesher accommodates a graft only 13.5 cm (5.3 inches) long, a longer graft can be meshed in sections.

The Zimmer mechanical skin mesher (Zimmer Meshgraft Dermatome, Zimmer, Warsaw, Ind) is a more elaborate and expensive meshing instrument, capable of expanding the graft to one and one-half, three, six, or nine times its original area. The graft is positioned dermal side down on a specially grooved plastic carrier selected according to the degree of expansion desired, and the graft and carrier are fed through the mesh cutter by turning a hand-crank (Fig. 25-13). The pattern engraved onto the plastic carrier determines the distance between cuts. The graft must be placed on the ridged surface of the carrier, because placing the graft on the smooth side of the carrier causes the graft to be shredded into spaghetti-like strips.

An important consideration when purchasing a mesh graft dermatome is the width of grafts routinely harvested with the skin graft dermatome. Grafts up to 100 mm wide are harvested routinely with a free-hand skin graft knife, but a graft wider than 76 mm is difficult to mesh with a Zimmer mechanical skin mesher. Grafts up to about 110 mm wide can be fitted onto the cutting surface of the Padgett mechanical skin mesher. Although the Padgett mechanical skin mesher accommodates a graft only 13.5 cm (5.3 inches) long, a longer graft can be meshed in sections.

An expanded, meshed graft has the appearance of chicken wire or chain-link fencing and uniformly exposes portions of the wound within the fenestrations (Fig. 25-14). The amount of wound exposed within the fenestrations depends on the degree to which the graft is expanded. Portions of the wound covered by the graft heal primarily, but each portion of the wound exposed within the fenestrations must heal by contraction and epithelialization. The exposed portions of the wound epithelialize rapidly because of the...
enormous increase in the border of the graft from which epithelial cells migrate.\textsuperscript{54,56} The epithelium that eventually covers the expanded fenestrations has no adnexa, causing the wound to heal with abundant, diamond-shaped epithelial scars. The more a graft is expanded at application, the more apparent are the diamond-shaped scars.\textsuperscript{2,38,54,56} The size of the epithelial scars can be reduced by attaching the graft to the wound so that the fenestrations within the graft are parallel with the skin lines (i.e., parallel to the long axis of the limb).\textsuperscript{55} The diamond-shaped epithelial scars within the grafted wound diminish in size as the grafted wound contracts.

\section*{Applying Sheet Grafts}

Excess granulation tissue should be excised before the graft is harvested, to allow time for hemorrhage to stop before the graft is applied. Excising exuberant granulation tissue 24 hours in advance of grafting ensures hemostasis and provides time for budding capillaries to develop at the surface of the wound for rapid vascularization of the graft\textsuperscript{43} (see \ref{Preparation of the Recipient Site}, earlier). If granulation tissue is not exuberant, the surface of the wound should be rubbed with a gauze sponge or gently scraped with a scalpel blade held 90 degrees to the wound, until serum exudes from the wound’s surface.

The graft should be situated on the wound so that the direction of its hair growth conforms to that of the surrounding skin. A graft harvested with the horse anesthetized can be sutured or stapled to the wound’s margin before the horse is allowed to recover from anesthesia. To avoid constant disturbance of the fibrin seal at the edge of the graft when securing the graft with sutures, the suture needle should pass from the graft to the surrounding skin, rather than from the surrounding skin to the graft.\textsuperscript{23} To suture or staple the graft to the wound’s margin with the horse standing, the margin of the wound must first be desensitized using local or regional anesthesia. The graft can be fixed to the margin of the wound, with the horse standing, without using local or regional anesthesia, by overlapping and gluing the margin of the graft to the margin of the wound with cyanoacrylate glue (SuperGlue, Loctite Co, Cleveland, Ohio), provided that sufficient skin has been harvested to allow overlap of the graft (Fig. 25-15). Applying the graft with the horse standing reduces the time of general anesthesia and eliminates the possibility of damage to the graft that may occur while the horse recovers from general anesthesia.

A graft need only be fixed to the wound’s margin, because fibrin produced by the wound fixes the graft to the wound’s surface within minutes after the graft is applied.\textsuperscript{2,26} If the wound is large or is in an area that is difficult to immobilize, however, such as the dorsum of a fetlock, the graft can be further secured, with simple interrupted sutures placed through the fenestrations in the meshed graft. To suture a graft to the bed of a fresh wound, with the horse standing, the wound must first be desensitized with regional or local anesthesia. A graft can be sutured to granulation tissue, with the horse standing, without anesthesia, because granulation tissue has no innervation (Fig. 25-16). Sutures can be removed in 6 or 7 days when acceptance of the graft is ensured. Catgut is convenient to use as a suture because it...
swells, causing the knot to loosen. If tied with a square knot, the suture can usually be removed by applying gentle traction to one end of the suture with a hemostat. Removing sutures in this fashion is easier than cutting the sutures.

**Acceptance and Cosmesis**
The thickness of a graft greatly influences its acceptance at the recipient wound. The thinner the graft, the less are its metabolic demands, and the less are its demands for vascularity at the recipient bed. Blood vessels branch as they ascend the dermis, so the thinner the graft is, the greater the number of exposed vessels. The greater the number of exposed vessels, the better is the absorption of nutrients from the recipient wound, and the more rapid is revascularization from inosculation. The thinner the graft, the poorer is its durability and cosmetic appearance.

Split-thickness grafts obtained from the hip, gaskin, or ventral aspect of the abdomen of horses that are 0.5 mm (0.020 inch) or less thick lack durability and have sparse or no hair coverage. Split-thickness grafts harvested from these areas and from the ventrolateral aspect of the thorax that are between 0.63 mm (0.025 inch) and 0.76 mm (0.030 inch) thick have moderate to good piliation and good durability. The thickness to which the graft should be harvested is a matter of judgment, because the thickness of the dermis varies between horses and between donor sites. Although one of the aims of split-thickness grafting is to provide adequate piliation at both the donor and recipient sites, occasionally piliation is inadequate at either site.

**Island Grafts**
An island graft is a small piece of full-thickness or split-thickness skin, placed either into or onto a granulating wound. Other names for this type of graft include implantation graft and seed graft. Implanting island grafts into granulation tissue of horses, rather than applying them to the surface of the wound, avoids shearing forces between the graft and the bandage. The purpose of island grafting is to increase the area of epidermis from which epithelialization can proceed; consequently, wounds that receive island grafts heal primarily by epithelialization. Types of island grafts used to graft wounds of horses are the punch graft, the pinch graft, and the tunnel graft.

**Punch Grafts**
Punch grafts are small, full-thickness plugs of skin that are harvested and implanted into granulation tissue using skin biopsy punches. Punch grafts can be taken directly from the horse or from an excised, full-thickness sheet of skin.

Common donor sites for obtaining punch grafts directly from the horse are the ventrolateral aspect of the abdomen, the perineum, and the portion of the neck that lies beneath the mane. The donor site is clipped, scrubbed, and desensitized with a local anesthetic agent. The perineal area can be desensitized using caudal epidural anesthesia. Removing punch grafts directly from the horse with a skin biopsy punch creates small blemishes at the donor site (Fig. 25-17). Therefore, the grafts should be harvested in a symmetrical pattern about 1 cm apart to improve cosmesis. The small wounds created by the biopsy punch need not be closed, but suturing or stapling each wound may produce less obvious blemishes.

Subcutaneous fascia and fat should be sharply excised from each individual graft before it is implanted to facilitate plasmatic imbibition and revascularization. Removing subcutaneous tissue from each small plug of skin is a tedious process. One method is to stretch the subcutaneous tissue between two thumb forcesps grasping the top of the plug and another thumb forcesps grasping the subcutaneous tissue. A second person excises the taut subcutaneous tissue from the dermis with a scalpel blade.

Punch grafts can also be harvested from an elliptical, full-thickness sheet of skin, which is usually harvested from the cranial pectoral area, where the skin is relatively mobile. A 10-cm-long by 4-cm-wide section of skin provides enough punch grafts to cover most wounds and allows easy primary closure of the donor site. The section of skin is stretched and secured, epidermal side down, to a sterile piece of cardboard or Styrofoam or to a sterile polypropylene block. After all subcutaneous tissue is sharply excised from the section of skin, full-thickness plugs are cut from the skin using a 6- to 7-mm-diameter skin biopsy punch (Fig. 25-18). The grafts are stored on a gauze sponge moistened with physiologic saline solution until they are implanted, and the wound created at the donor site is closed in one or two layers. Applying a stent to the sutured wound decreases tension on the suture line.

Exuberant granulation tissue at the recipient site should be excised to the level of the margin of the wound 24 to 48 hours prior to grafting. The recipient holes in the granulation tissue should be created before the grafts are harvested to allow hemostasis to occur prior to implantation. The depth of the recipient holes should correspond to the thickness of the grafts to be inserted. To avoid obscuring the wound with hemorrhage that occurs when the recipient

---

*References 8, 15, 20, 23, 27, 38, 53.*
holes are created, creation of the recipient holes should begin distally and proceed in a proximal direction. A cotton-tipped applicator inserted into the recipient holes enables each hole to be located easily for insertion of a graft and prevents a blood clot from forming in the hole (Fig. 25-19). Spraying the wound with phenylephrine before creating the recipient holes may improve visibility by decreasing hemorrhage. Creating the recipient holes hours in advance of implantation ensures a hemorrhage-free wound for grafting. The holes should be placed about 6 mm (about 1/4 inch) apart in a symmetrical pattern. The recipient holes are created with a slightly smaller biopsy punch than that used to harvest the grafts, to allow for contraction of the graft. For example, if the grafts are harvested with a 7-mm-diameter biopsy punch, the recipient holes should be created with a 5-mm biopsy punch (Fig. 25-20). The grafts are inserted into recipient holes, and the grafted wound is covered with a nonadherent dressing and a bandage. Consideration can be given to the direction of the hair growth on the graft when the graft is inserted, but the cosmetic outcome is little affected by properly orienting the direction of the hair.

The pigmented, superficial portions of the grafts frequently slough, exposing nonpigmented deeper layers. By 3 weeks, each plug of skin is surrounded by a red ring, which represents migrating epithelium. Acceptance of the grafts is ensured if the grafts remain within the recipient hole, but survival of 60% to 75% of the grafts is a realistic expectation. The time required for the wound to completely epithelialize is inversely proportional to the amount of wound covered by viable plugs. Punch grafting requires no expensive or sophisticated equipment and little expertise, and the grafts are accepted into recipient beds that are unsuitable for sheet grafting. Punch grafting can be performed with the horse standing, making this an inexpensive method of grafting wounds. Punch grafting is usually reserved for small wounds where cosmesis is not important. Wounds healed by punch grafting are covered primarily by an epithelial scar from which grow sparse tufts of divergent hair (Fig. 25-21).

Pinch Grafts

Pinch grafts are small discs of skin, harvested by excising an elevated cone of skin, that are laid onto or implanted into granulation tissue. The pinch graft is sometime referred to as a Reverdin graft. The donor sites for obtaining pinch grafts from the horse are the same as described for punch grafts; small blemishes created at these donor sites are relatively inconspicuous. A disc of optimal size is approximately 3 mm in diameter, which approaches full thickness toward its center, but its thickness diminishes toward its periphery.

Preparation of the donor site is identical to that described for punch grafts. A cone of skin is elevated using a tissue forceps, a suture needle, or a hypodermic needle with a bent point, and it is excised with a scalpel blade (Fig. 25-22). A no. 11 scalpel blade is most suited for...
in advance of implantation to ensure a hemorrhage-free wound for grafting, but locating the pockets after hemorrhage has ceased may be difficult.

To implant a graft, a no. 15 scalpel blade is stabbed into the granulation tissue of the recipient bed at an acute angle to create a shallow pocket into which the graft is inserted. Implantation should begin distally and proceed proximally, because the pockets are obscured by hemorrhage after they are created. The grafts should be implanted about 3 to 5 mm apart. Each graft is laid onto the wound, epidermal side up, proximal to the pocket and slid into the pocket using a hypodermic needle, a straight suture needle, or the scalpel blade used to create the pocket. Consideration can be given to the direction of the hair growth on the graft when the graft is inserted, but the cosmetic outcome is little affected by properly orienting the direction of the hair. To speed implantation, three or more grafts can be laid onto the granulation tissue at once, each 15 to 20 mm proximal to its proposed site of implantation. Hydrostatic pressure prevents the grafts from falling from the wound. The surgeon creates a pocket distal to a graft and inserts the graft into the pocket using the same scalpel blade that was used to create the pocket. The surgeon can create and implant the pockets in rapid succession without looking away from the wound.

Wounds created at the donor site are left to heal by second intention or closed with a single suture or staple. The grafted wound is covered with a nonadherent dressing and a bandage.

The thin layer of granulation tissue covering each pinch graft usually sloughs between the first and second week after grafting. Grafts initially appear as dark spots on the wound’s surface (Fig. 25-23), but frequently the superficial, pigmented portion of the graft sloughs, causing the graft to appear as a white spot surrounded by pink granulation tissue. Within 3 weeks, each disc of skin is surrounded by a red ring, which represents migrating epithelium. Epithelium migrates from the margin of the wound, as well as from the margin of each graft, so that eventually the entire wound is
covered with epithelium. Even under adverse conditions, one can expect at least 50% to 75% of the grafts to survive. Pinch grafting, like punch grafting, is a relatively inexpensive technique of grafting, because the procedure can be performed with the horse standing, and because only basic instruments are required. Little expertise is necessary, and the grafts can survive in a granulation bed that is less than ideal. Pinch grafting is tedious, however, and imparts a poor cosmetic appearance, because the wound is left covered by an epithelial scar from which grow sparse tufts of divergent hair.

Tunnel Grafts

Tunnel grafts are strips of split-thickness or full-thickness skin implanted into tunnels created in granulation tissue. The grafts are exposed days later, when they have revascularized, by excising the overlying granulation tissue that forms the roof of the tunnel. Donor skin can be harvested from various sites on the horse, using various techniques, and implanted with the horse anesthetized or standing and sedated.

Split-thickness or full-thickness strips of skin can be harvested conveniently from the portion of the neck that lies beneath the mane or the ventral aspect of the flank. In preparation for harvesting strips of skin, linear wheals, 2 to 3 cm wide and slightly longer than the wound to be grafted, are created along the longitudinal axis of the donor site by subcutaneously injecting local anesthetic solution (or physiologic saline solution, if the graft is to be harvested with the horse anesthetized).

A straight intestinal forceps is applied to the base of each wheal so that skin protrudes slightly above the jaws of the forceps. If a strip of skin longer than the jaws of the forceps is required, two intestinal forceps are applied end-to-end to the base of the wheal. The thickness and width of the graft is determined by the amount of skin that protrudes above the jaws. The protruding skin is severed with a scalpel (Fig. 25-24). If the excised strip of skin is full thickness, subcutaneous tissue attached to the dermis is sharply excised. The donor sites are closed with sutures or staples.

To implant a strip of skin in the granulation bed, the end of a long, thin, rat-tooth, alligator forceps is inserted into granulation tissue at the edge of the wound and advanced through the granulation tissue at a depth of about 5 or 6 mm until it emerges at the opposite margin of the wound. One end of the graft is grasped in the jaws of the forceps, with the epidermis positioned toward the surface of the wound, and pulled through the tunnel. The grafts should be embedded at right angles to the convex surface of the wound to aid entry and exit of the forceps. A wound that is not convex is more easily grafted if granulation tissue is allowed to proliferate so that it protrudes slightly above the margin of the wound. The strips should be embedded about 2 cm apart.

The strip of skin is embedded in two steps if the alligator forceps is not long enough to completely span the wound, or if the wound is too convex for the alligator forceps to completely span it. In either case, the forceps is advanced through the granulation tissue as far as possible and exited, one end of the graft is grasped, and the forceps is pulled back through the tunnel, with the graft in tow (Fig. 25-25). The end of the forceps is reinserted into the granulation bed at the opposite margin of the wound and advanced beneath the surface of the granulation tissue until...
it emerges at the site of exit of the graft. The end of the graft is grasped in the jaws of the forceps, and the forceps, with graft in tow, is pulled back through the second tunnel.

The graft can also be embedded by positioning the strip of skin onto a strip of adhesive tape, with the epidermis next to the tape. The purpose of the adhesive tape is to prevent the edges of the strip from folding inward and to act as a guide when the grafts are later exposed. The tape should extend 5 cm beyond one end of the strip, and excess tape at this end is folded over the skin so that about 1 cm of the end of the strip is covered by tape. Excess tape along the graft’s margin is trimmed with scissors. The tape-covered end of the graft is fitted through the eye of a 10- to 12-cm cutting needle with a flat curve, and the graft–tape composite is implanted by advancing the needle beneath the surface of the granulation bed. If the needle is not long enough to span the wound completely, or if the wound is too convex for the needle to completely span it, the needle is advanced beneath the bed as far as possible, exited, and reentered at the point of exit for a second bite. Another method of creating the strips of graft and tape is to lay a sheet of split- or full-thickness skin, hair side down, onto the sticky side of a similarly sized sheet of adhesive tape; strips of skin and tape are cut from this composite.

The exposed ends of the embedded strips are attached to the margin of the wound with a suture, staple, or cyanoacrylate glue, and the wound is covered with a nonadherent dressing and a pressure wrap. Six to 10 days after grafting, the roof of each tunnel is removed, with the horse sedated or anesthetized, to expose the grafts, and if necessary, to remove adhesive tape.

To remove the roof of a tunnel, a smooth, malleable probe is inserted into the tunnel superficial to the graft, and a V-shaped strip of granulation tissue is carefully excised over the probe with a scalpel blade to expose the graft. The roof of each tunnel can also be sawed off using a twisted, doubled piece of fine wire threaded through the tunnel.

Accidentally removing a graft while attempting to expose it or failure to locate buried grafts can detract from the success of tunnel grafting. These complications can best be avoided by applying a tourniquet proximal to the wound to enhance visibility, or by exposing the grafts with the horse anesthetized. Placing the grafts closer than 2 cm apart may affect the viability of granulation tissue surrounding the grafts. About 60% to 80% acceptance of the strips can be expected.

Tunnel grafting is recommended primarily for wounds located in areas where immobilizing other types of grafts would be difficult, such as the dorsal aspect of the hock. Tunnel grafts are unaffected by movement in highly mobile areas, because the grafts are circumferentially encompassed and immobilized by granulation tissue. Tunnel grafting does not require expensive equipment and can be performed with the horse standing, but the technique requires the presence of a granulation bed, and aspects of this technique, especially removing the top of the tunnels, make tunnel grafting relatively tedious.

**AFTERCARE OF THE DONOR SITE**

The donor site of a split-thickness graft retains a portion of the dermis and is comparable to a deep abrasion.

Blood and fibrin form a scab over the abrasion, and beneath this scab, epithelial cells from the wound’s edge and epithelial cells produced by adnexa in the remaining dermis migrate to cover the surface of the abrasion. The wound at the donor site is usually covered by epithelium within 1 to 3 weeks, depending on the depth of the cut (Fig. 25-26).

The new, pink epithelium covering the donor site begins to develop pigment within a month after it forms, causing the epithelial scar to become black. The quantity of adnexa is greatest in the upper layers of the dermis, and consequently, healing of the donor site proceeds more quickly when a thin skin graft is harvested. When grafts between 0.63 mm and 0.76 mm thick are harvested from the horse, the donor site heals with a noticeable epithelial scar.

Pain caused by exposure of nerves at the donor site of a split-thickness graft can be reduced by bandaging the donor site, but split-thickness grafts of horses are virtually always taken from an area that is difficult to bandage. Pain can be decreased by covering the donor site with fine-mesh gauze or a biologic bandage, such as a stored allograft or xenograft (see “Allografts and Xenografts” and “Storage of Grafts,” later). The gauze or biologic bandage falls off when the donor site is completely epithelialized. An uncovered donor site develops a scab, and this scab should not be removed. Any attempt to remove the scab is met with violent resistance from the horse, and its removal interferes with epithelialization that proceeds beneath it. An analgesic drug, such as phenylbutazone, should be administered before the graft is harvested and for several days after surgery.

**AFTERCARE OF THE RECIPIENT SITE**

The grafted wound should be covered with a sterile, nonadherent dressing, such as cotton nonadherent film dressing (Telfa Sterile Pads, Kendall Co, Hospital Products, Boston, Mass), rayon polyethylene dressing (Release, Johnson & Johnson Products, Inc, New Brunswick, NY), or petrolatum-impregnated gauze dressing (Adaptic, Johnson & Johnson Inc, Fort Dodge, Iowa). Petrolatum-impregnated gauze dressings can be prepared by steam-autoclaving a container filled with gauze sponges topped with a dollop of petrolatum. The petrolatum impregnates the gauze as it melts.

![Figure 25-26](image)

**Figure 25-26.** The donor site of a split-thickness graft 2 weeks after the graft was harvested. The donor site is nearly covered by epithelium. The new, pink epithelium will begin to develop pigment within a month, causing the epithelial scar to become black.
wide weave of a gauze sponge, however, makes the sponge more likely to adhere to the grafted wound than would a commercially available petrolatum-impregnated gauze dressing with a close weave (my observation).

The primary dressing is secured to the grafted wound with sterile, elastic, conforming, rolled gauze. If the grafted wound is in an area that is difficult to immobilize, such as the dorsal aspect of the hock, securing the primary dressing with staples or with elastic adhesive tape, rather than rolled gauze, may help to decrease shearing forces between the graft and the bandage. The secondary layer of the bandage should be bulky, to decrease motion of the limb, and absorbent, to wick bacteria and destructive enzymes from the grafted wound. Immobilizing the limb with a cast is usually not necessary unless the grafted wound is located in a highly mobile area, such as the dorsum of the fetlock. A splint or a Robert Jones bandage applied to the limb usually immobilizes the grafted wound sufficiently.

The bandage should not be changed for 4 or 5 days after grafting, unless virulent, nosocomial infections are a common problem in the hospital, because changing the bandage may disturb the graft’s delicate attachment to the wound. However, if such infections are a common problem in the hospital, the bandage should be changed daily, or even twice daily, for at least 5 days. Changing the bandage daily allows exudate, which contains destructive enzymes, to be removed from the wound, and it allows application of an appropriate antimicrobial drug to the wound. Complete loss of a sheet graft, from infection or motion, later than 5 days after grafting is uncommon. Streptococci or pseudomonads of a sheet graft, from infection or motion, later than 5 days appropriate antimicrobial drug to the wound. Complete loss of a sheet graft, from infection or motion, later than 5 days after grafting is uncommon. Streptococci or pseudomonads of a sheet graft, from infection or motion, later than 5 days.

In the hospital, the bandage should be changed daily, or even twice daily, for at least 5 days. Changing the bandage daily allows exudate, which contains destructive enzymes, to be removed from the wound, and it allows application of an appropriate antimicrobial drug to the wound. Complete loss of a sheet graft, from infection or motion, later than 5 days after grafting is uncommon. Streptococci or pseudomonads can quickly destroy a recently applied graft (Fig. 25-27), so prompt recognition of infection and application of an appropriate antimicrobial drug to the grafted wound are necessary. Exudate that develops on a grafted wound should be cultured for bacterial growth, and isolates should be tested for antimicrobial susceptibility. Until the results are known, a broad-spectrum antimicrobial agent, effective against both β-hemolytic streptococcus and Pseudomonas, such as a combination of ticarcillin disodium and clavulanate potassium, should be applied topically to the wound.

If the limb has been immobilized in a cast, and if nosocomial infection from streptococci or pseudomonads is a common problem in the hospital, an antimicrobial drug should be applied periodically to the wound through an infusion tube fixed to the grafted wound and exited through the top of the cast. A good infusion tube can be prepared from silicon tubing by sealing its distal end and perforating it (with a 25-gauge needle) in multiple places along the portion that lies adjacent to the wound. Even a docile horse should be heavily sedated during the initial bandage changes to help avoid movement that may disturb the delicate, vascular connections forming between the recipient bed and the graft. Adherence of the primary dressing to the grafted wound by fibrin that exudes through a meshed graft usually indicates that the graft is well adhered to the wound by a fibrin seal. Soaking the primary dressing with physiologic saline solution may ease removal of the dressing, but if the primary dressing cannot be removed easily, it should be left in place.

Exuberant granulation tissue that inhibits epithelial migration may grow through the latticework of a meshed graft, especially if the graft was applied to the wound fully expanded. A corticosteroid applied to the grafted wound causes the exuberant granulation tissue within the graft to regress, allowing epithelial migration to proceed, even if at a slower than normal pace.

Ideally, grafted wounds on limbs should be protected by a bandage until epithelialization is complete. If bandaging becomes impractical before epithelialization is complete, small, nonepithelialized areas within the grafted wound can be allowed to heal beneath a scab, which soon forms when the wound is left exposed.

A grafted wound in an area that is difficult to wrap, such as the abdomen or thorax, can be protected with a “tie-over” bolus dressing, sometimes referred to as a stent. To apply a stent, the grafted wound is covered with a non-adherent dressing followed by a bolus of gauze. Long ends of interrupted sutures, placed around the margin of the grafted wound, are tied tightly over the bolus (Fig. 25-28).

Pressure on a graft from a bandage is not necessary for the graft to be accepted, so, for areas that are difficult to bandage or for wounds that are chronically plagued with infection, the grafted wound can be left uncovered. “Open” grafting avoids shearing forces imposed by a bandage and avoids maceration of the graft by allowing constant drainage of exudate. To successfully employ open grafting, precautions, such as tying the horse or applying a neck cradle, must be taken to prevent the horse from disturbing the exposed graft.

Some horses probably suffer from hyperesthesia at the grafted wound, so, when bandaging is discontinued, temporarily applying a neck cradle or tying the horse may be prudent to prevent the horse from mutilating its grafted wound. Drying and scaling of the healed donor and recipient sites of a split-thickness graft, caused by reduced con-
The use of cutaneous porcine xenografting in humans arose from the need for a substitute for allografts as a biologic dressing because of the short supply of cadaveric skin, but clinical comparisons in humans have shown that cutaneous porcine xenografts are inferior to cutaneous allografts.11 Cutaneous porcine xenografts are more poorly adhered than allografts, allow higher bacterial counts in the wound, and cause a more intense immunologic rejection.

**STORAGE OF GRAFTS**

Autografts or allografts can be applied successfully to wounds after being stored for several weeks at refrigeration temperature, in gauze that has been soaked in either physiologic saline solution or lactated Ringer’s solution.12,69-71 Skin can be stored in a refrigerator, for much longer periods in a nutrient medium, such as McCoy’s 5A Medium (Gibco Laboratories, Inc, Grand Island, NY) to which serum has been added.71,74-76

McCoy’s 5A Medium is a tissue-culture medium composed of a balanced electrolyte solution to which amino acids, vitamins, dextrose, and a pH indicator (phenol red) have been added. Adding vitamins, amino acids, dextrose, and serum to the electrolyte solution greatly extends the time that a graft can be stored. Skin from humans has been stored successfully in refrigerated nutrient media for 6 to 8 weeks.71,74-76 Wounds of horses have been grafted using split-thickness skin grafts refrigerated at 4°C in a solution of McCoy’s 5A Medium and horse serum for 3 weeks, with consistently successful results,74 and wounds of some horses have been grafted successfully using skin stored for as long as 12 weeks.

The concentration of serum in the storage medium should be between 10% and 33%.77 A concentration of serum greater than 33% stimulates the metabolic activity of the graft. Antigenic reaction of the serum to the graft is avoided by using a commercially available antibody-free serum (GG-Free Horse Serum, Gibco Laboratories, Inc, Grand Island, NY), pooled homologous serum, or the horse’s own serum.76 The stored grafts should be allowed access to air.71

To prepare a meshed split-thickness skin graft for storage, the graft is laid on a sterile gauze swab or gauze dressing, with the epidermis of the graft next to the gauze. The gauze–graft composite is rolled up, with the gauze to the outside of the roll (Fig. 25-29), and placed in a sterile container containing approximately 1 to 2.5 mL of the storage medium for each square centimeter of stored graft.15,27 The storage medium should be examined occasionally for a color change brought about by a change in pH. A color change in the McCoy’s 5A Medium from cherry-red to orange-yellow indicates excessive accumulation of catabolites and the need for immediate application of the graft or replacement of the medium. Only half of the volume of medium should be replaced, because total replacement affects the graft deleteriously.76

A split-thickness skin graft, harvested while the horse is anesthetized for treatment of a wound, such as removal of a bone sequestrum, can be stored until the wound’s condition has improved enough to permit grafting.15,78,79 A graft can be
stored for delayed grafting of an excisional defect accompanied by excessive hemorrhage. Storing the graft, so that it can be applied with the horse standing, shortens the anesthetic period and eliminates the risk of the graft's being disturbed during recovery. A stored graft is often more readily accepted than a fresh graft, because grafts stored for 24 hours or more release anaerobic metabolites that stimulate rapid revascularization of the graft. For this reason, a stored graft is sometimes referred to as a "prepared graft."

A stored graft is useful for covering a defect created when all or a portion of a primary graft sloughs, and for this reason, harvesting more skin than is required to cover a wound is often prudent, especially when grafting has a greater than usual possibility of failure. A stored graft not required for autografting can be used as a biologic dressing for a wound of another horse, when circumstances permit.

The skin is the largest organ in the body and is very adaptable to the environment. The main functions of the skin are to protect against wear and bacterial invasion, to aid in thermal regulation, and to prevent water loss.\textsuperscript{1,2}

The anatomy of the equine skin was first completely described by Talukdar and colleagues in 1972.\textsuperscript{3} Using normal horses of ages 2 to 17, they collected skin from 49 different areas. The average skin thickness of the body skin was 3.8 mm, the skin near body openings 3.3 mm, and the skin at the main and tail 6.2 mm. Skin was thicker in older geldings than in younger horses and at the extensor surface of the legs than at the flexor surface of the legs. In general, the skin of the horse is thicker than that of swine, goats, and sheep; thinner than that of beef cattle; and similar in thickness to that of dairy cattle.\textsuperscript{3}

The epidermis is composed of four layers: the stratum basale, stratum spinosum, stratum granulosum, and stratum corneum (Fig. 26-1). The stratum corneum slows water loss and functions as a barrier to harmful substances. Other cells found in the epidermis include melanocytes for production of melanin, Merkel cells for mechanoreception of light touch, and Langerhans’ cells to help fight infection by engulfing foreign material. The dermis is separated into two layers, the superficial papillary layer and the deep reticular layer, and it provides support for the epidermis. The dermis in the lumbar, sacral, and gluteal regions has a third layer of collagenous fibers. The dermis also contains a rich vascular network that supplies the skin with a continuous blood supply. The vascular system is very important in temperature regulation, access of nutrients to the skin, absorption of topical medications, delivery of systemic medications, and the healing of wounds (see Chapter 5). The main vascular supply comes from the subcutaneous area. In the thinner-skinned areas, the hair angle is more acute. The hair follicles in the general skin areas where the hair length changes with the season are shorter than the hair follicles in the areas of mane and tail. In most cases, two sebaceous glands are associated with each hair follicle. The sweat glands are apocrine.\textsuperscript{2,3} The hairs are surrounded by nerves that provide sensation by responding to pressure on the hair shaft. The primary nerve supply comes from the subcutaneous region.

Cleavage lines (Langer’s lines of tension:—see Chapter 24) have been described in many species. The pattern is determined by placing an awl through the epidermis into the dermis and observing the orientation of the split or cleavage formed.\textsuperscript{4} In a review, Rooney\textsuperscript{4} cites the work of Schouppe,\textsuperscript{5} who studied cleavage lines. Schouppe found that horses had cleavage lines whose orientation was parallel to the predominant orientation of the collagen fibers. These cleavage lines changed very little between adult horses, and wounds that healed best were parallel to the cleavage lines. In general, the cleavage lines were parallel to the long axis of the legs, head, and torso, and perpendicular to the long axis of the neck and flank. This is different from the cleavage lines found in dogs, which look more like stripes on a tiger.\textsuperscript{6} In my opinion, cleavage lines on horses more closely approximate those of dogs than was reported by Schouppe (see Fig. 24-1). When possible, incision lines should be made parallel to the cleavage lines.

\textbf{FIRST AID}

Appropriate wound care is always a balance between improving the wound environment and harming the cells that are integral to the healing process. Consequently, the veterinarian must carefully weigh the benefits and the detriments of any particular action, not only for the immediate results but also for the long-term healing process.

\textbf{ASSESSMENT}

Wound assessment is one of the most important steps in wound therapy. More repaired wounds fail because of improper preparation and assessment than because of improper therapy. Properly preparing the wound provides an accurate assessment of the wound and deeper structures. Wound preparation begins with placing the animal in a location and environment that will allow the clinician to best determine the status of the wound. If the environment is not adequate to perform all of the tasks in the following paragraphs, it may be a good idea to move the horse to a place where these procedures can be done more efficiently and easily.
INITIAL MANAGEMENT
Restraint and Analgesia
For the horse with a wound, many types of restraint are appropriate, from simply holding its head to general anesthesia. Before using sedation, the horse’s systemic status should be determined. It is uncommon for a horse to lose enough blood to cause problems with sedation, but if this is the case, the horse may collapse. Many commonly used sedative agents cause hypotension. Physical examination, blood work including packed cell volume, and skin turgor testing can help determine the systemic status of the horse and allow the clinician to decide if sedation is feasible (see Chapters 1, 4, and 8). Alternatives to systemic sedation include manual restraint such as a twitch, or local anesthesia of the affected area. In many cases, local anesthetic agents provide the best opportunity to prepare and examine the affected area, and to eventually treat the wound.7

Initial Preparation
After the horse has been restrained appropriately and the area has been desensitized with local anesthetic, the clinician decides whether to treat the wound with aseptic technique or if a simple clean technique is adequate. If there is a possibility of cross-contaminating a wound while preparing and exploring, aseptic technique should be used. The next step is to clip the hair over and around the wound site. To minimize the amount of clipped hair that gets into the wound, it can be covered with water-soluble, sterile, lubricating gel prior to clipping. It is best to put on a pair of examination or sterile gloves, apply the gel onto the fingers, and rub the gel into place (Fig. 26-2). This technique generally ensures that the gel will remain in contact with the wound bed. As the hair is clipped, it is trapped in the gel. The gel with the trapped hair can simply be rinsed from the wound with water or saline. Only when the entire wound area has been clipped and prepared can the clinician begin to fully appreciate the complexity of the wound. In many cases, seemingly insignificant wounds had invaded synovial structures, and because appropriate aggressive therapy was not instituted, the horse was eventually euthanized.

DÉBRIDEMENT
Débridement is an effective way to reduce the bacterial load within a wound and to minimize necrotic tissue. The benefits of débridement have been widely discussed in the field of human wound care.8 Necrotic tissue and bacterial infection are major roadblocks to effective and cosmetic wound healing. The presence of foreign material reduces the number of bacteria necessary for infection by a factor of 10 (i.e., from $10^5$ to $10^4$ bacteria per gram of tissue). Each type of débridement has positive and negative consequences for wound healing, and it is important to select the technique that provides the best benefit-to-detriment ratio. The most common types of débridement are sharp, mechanical, chemical, and autolytic.

Sharp Débridement
Sharp débridement is one of the least traumatic methods available to the equine clinician, yet it is often underutilized. The major drawback to sharp débridement is that once the tissue is removed, it cannot be put back, so it is wise to be conservative in the removal of tissue. If the margin between viable and nonviable tissue is not clear, it is often better to leave some tissue for removal at a later time if necessary. Many skin flaps, especially on the head, retain viability even though they are cool at presentation. Tools for sharp débridement include a scalpel, scissors, and lasers. Scalpel débridement is the least traumatic of these techniques (Fig. 26-3), and it should be used whenever possible in the initial

Figure 26-2. Application of sterile water-soluble gel to wound before clipping.

Figure 26-3. Sharp débridement of a wound on the dorsal and lateral aspect of the pastern region.
wound treatment stages. Other types of sharp débridement play a more secondary role.

**Mechanical Débridement**

Mechanical débridement is more traumatic, and unfortunately it is probably the most commonly used method in the horse. It can be performed using woven gauze (Fig. 26-4), lavage (Fig. 26-5), wet-to-wet, or wet-to-dry dressings. Mechanical débridement can be a useful tool, and it can be beneficial in the healing process, but it can be very traumatic. Often, when using gauze, too much pressure is applied and trauma to the wound bed ensues. Only gentle pressure should be used. If more aggressive débridement is necessary, sharp débridement should be performed. Woven gauze provides mechanical débridement characteristics superior to those of nonwoven gauze (Fig. 26-6).

Lavage can be used successfully for mechanical débridement. It involves two critical components, the selection of a noncytotoxic cleansing solution and the delivery of that solution to the wound surface with appropriate pressure and volume to wash away the necrotic debris without pushing it further into the tissue planes of the wound. The pressure should be between 10 and 15 pounds per square inch (psi). One way to achieve this pressure is to attach a 19-gauge needle or catheter to a 35-mL syringe. Many devices are available. Showerheads are safer and more effective than single-jet lavage systems. Therefore, devices that produce high pressures (e.g., the WaterPik) should not be used. A simple, gentle, low-pressure lavage system can be made by using a 16-gauge needle to punch four to eight holes in the cap of a 1-L bottle and then squeezing saline out (Fig. 26-7, and see Fig. 26-5).

The fluids most commonly used in veterinary medicine are dilute antiseptics. However, there is no evidence that dilute antiseptics successfully kill bacteria when there is...
necrotic tissue in the wound. To achieve bacterial killing in necrotic tissue, high concentrations of antiseptic are necessary, and high concentrations have a negative effect on the cells necessary for wound healing. Antiseptics are best used around the wound, but not in the wound. Saline has been shown to be effective in reducing bacterial counts in an infected wound but to have no effect on wound healing in clean wounds. In one study comparing saline and water in an infected wound in a rat model, saline reduced the bacterial counts by 81.6% whereas tap water reduced bacterial counts by 82%. However, work by Buffa and coworkers suggests that tap water is very toxic to fibroblasts. When exudate is present, surfactant-based wound cleaners are more effective than saline or polyionic fluids (Fig. 26-8). In summary, the surgeon should avoid putting something in a wound that would not be tolerated in the eye or should not be consumed. If wound infection is present, sharp débridement together with systemic antibiotics is necessary to rid the host of bacteria. Local antibiotics, either by intravenous perfusion or topical, can also be helpful.

Wet-to-wet or wet-to-dry dressings can be used for mechanical débridement. Wet-to-wet dressings are intended to stay wet, whereas the wet-to-dry dressings are intentionally designed to dry out between bandage changes. Wet-to-wet dressing may have to be remoistened up to six times a day. These dressings are much more effective at removing necrotic tissue than is mechanical débridement using gauze, and the fibroblasts and epithelial cells suffer less damage. However, it is very time consuming and is generally available only in an intensive care hospital environment. Wet-to-dry dressings are performed by moistening the primary dressing (the dressing against the wound bed) with saline while leaving the rest of the dressings dry. The concept is that the absorbent secondary dressing will pull the fluid from the primary dressing, pulling the wound exudate into the primary dressing also. Because it is difficult to keep the primary dressing moist unless a large amount of exudate is produced by the wound, the primary dressing often becomes dry between bandage changes. When the dried primary dressing is removed, it effectively débrides the wound bed, and this débridement is very nonselective. Thus the usefulness of a wet-to-dry bandage is questionable. Primary dressings should never be allowed to become dry, as this reduces the effectiveness of autolytic débridement (see later) and leads to indiscriminate removal of epithelial cells and fibroblasts.

**Chemical and Enzymatic Débridement**

Chemical débridement has been used in many different forms in medicine. Dakin’s solution, a diluted sodium hypochlorite (bleach) solution, was originally used during World War I. Other chemical agents are hydrogen peroxide, acetic acid, and, more recently, hypertonic saline. Chemical débridement is nonselective and should be reserved for very contaminated wounds. However, although hypertonic saline is good in selected cases, sharp débridement is probably a better technique for removing large amounts of necrotic debris. Hypertonic dressings provide an effective chemical débridement with minimal damage to the wound in the early stages of wound healing (see “Second-Intention Healing,” later).

Enzymatic débridement involves placing enzymes directly onto the wound bed. The most commonly used enzymes are streptokinase/streptodornase, collagenase, DNase/fibrinolysin, papain/urea, and trypsin. Enzymatic débridement is limited when large amounts of necrotic tissue have to be removed and should be used only after an initial sharp débridement.

**Autolytic Débridement**

Autolytic débridement is the least traumatic of these techniques. It is achieved by leaving wound fluid (containing white blood cells and enzymes released from dead white blood cells) in contact with the wound bed. The white blood cells and enzymes affect only the dead and necrotic tissue, leaving healthy cells intact for wound healing. This can occur only in moist wounds (Fig. 26-9). When wounds are allowed to dry, autolytic débridement is slowed significantly. Autolytic débridement reduces the bacterial count by allowing access of white blood cells to the wound bed without causing continued trauma to the wound bed. However, sharp débridement should be performed before using autolytic débridement, as the latter technique is ineffective in the presence of large volumes of necrotic material.

**OPTIONS FOR WOUND CLOSURE**

The options for wound closure can generally be categorized as primary closure, delayed primary closure, and second-intention healing. To choose the most appropriate technique, the stages and classification of wounds must be understood.
There are four stages of wound healing: the inflammatory/cellular reaction stage, the débridement stage, the tissue formation/proliferation stage, and the maturation/remodeling stage. However, these stages overlap during the wound healing process (see Chapter 5). The duration and intensity of the inflammatory stage are generally determined by the extent of injury. For example, a surgical wound has a much shorter inflammatory stage than a severe degloving wound. The inflammatory stage is prolonged in the presence of necrotic debris, foreign material, or infection. The inflammatory stage should be reduced to the shortest amount of time possible. Extension of the inflammatory stage results in a delayed repair process.

The débridement stage begins early in the inflammatory stage and is marked by migration of neutrophils and macrophages into the wound site. The white blood cells phagocytize bacteria and enzymatically remove necrotic tissue. The length of this stage depends on the size of the wound and the amount of necrotic debris present. The débridement stage begins early in the inflammatory stage and is marked by migration of neutrophils and macrophages into the wound site. The white blood cells phagocytize bacteria and enzymatically remove necrotic tissue. The length of this stage depends on the size of the wound and the amount of necrotic debris present. The débridement stage begins early in the inflammatory stage and is marked by migration of neutrophils and macrophages into the wound site. The white blood cells phagocytize bacteria and enzymatically remove necrotic tissue. The length of this stage depends on the size of the wound and the amount of necrotic debris present.

The tissue formation (or proliferation) stage involves fibroblast migration and proliferation as well as epithelialization of the wound. The fibroblasts migrate into the wound along the fibrin scaffold. They secrete the ground substance of the wound as well as the collagen that will eventually provide tensile strength in the wound. Granulation tissue, which is highly vascular and important in wound contraction, quickly becomes evident in a noninfected wound. Wound contraction is the process by which full-thickness skin is drawn together by specialized fibroblasts known as myofibroblasts, which are similar to smooth muscle cells. Myofibroblasts cause thinning of the surrounding skin as they pull the wound edges together. Wound contraction, which is most effective in areas with excess skin, stops when cells of the same type are brought together, or when skin tension equals the ability of the myofibroblasts to contract. Epithelialization, which is part of the repair phase of the wound and begins early in the wound healing process, can be stopped with infection, drying of the wound surface, exuberant proliferation of granulation tissue, and repeated dressing changes.

The maturation stage of wound healing occurs when there is an equilibrium between collagen production and collagen destruction. It is during this stage that the collagen fibers are realigned along the lines of tension, and when wound tensile strength increases. The number of fibroblasts is also reduced.

Wound Classification

Wounds are typically classified on the basis of degree of contamination. Clean wounds, usually seen only in surgical situations, are not infected and do not involve the respiratory, alimentary, or urogenital tract. Clean contaminated wounds, generally seen in surgical situations, involve the lumen of the respiratory, alimentary, or urogenital tract. Contaminated wounds are generally traumatic in nature and may have gross contamination and necrotic debris. Infected wounds generally involve large numbers of bacteria, inflammation, edema, and suppuration. (For additional details on wounds, see Chapter 7.)

In summary, in the early stages of wound healing (i.e., in the inflammatory or débridement stage), wounds that are clean or clean contaminated are the best candidates for primary or delayed primary closure. Wounds that are in the later stages of healing or are contaminated or infected heal best by second intention.

BACTERIA IN WOUNDS

All wounds contain bacteria, but not all bacteria in wounds are cause for concern. Bacterial contamination describes the presence of bacteria in a wound without active multiplication or trauma to the host. Bacterial colonization indicates that the bacteria have attached to the tissue and are multiplying but are not necessarily causing trauma to the host. High numbers of bacteria in the absence of a host response may indicate an impaired immune response. Bacterial infection occurs when bacteria invade healthy tissue and actively multiply, overwhelming the host’s immune response.

Bacteriologic Assessment

One method of bacteriologic assessment used in equine practice is qualitative. Determining the types of bacteria in the wound, coupled with sensitivity testing, can guide the clinician in choosing antibiotics for treatment. The second method is quantitative. Bacterial counts greater than $10^5$ per gram of tissue are generally indicative of an active infection. The number of bacteria needed to produce an active infection is reduced if foreign material (e.g., suture, necrotic debris, a foreign body) is present, if the virulence of the...
bacteria is high, or if host resistance is decreased. Quantitative bacteriology is rarely performed in veterinary medicine; but if it should be considered when a wound is not progressing as anticipated or when a skin graft fails. Clinical observation is generally adequate for determining if a wound is infected. Signs such as discolored granulation tissue, edema in and around the wound, purulent exudate, odor, and lameness can indicate an infection. However, a wound can be infected without these overt signs. If infection is suspected, the wound should be cultured.

Technical Considerations in Contaminated Wound Closure

The three main strategies for preventing bacterial infection of wounds are effective wound cleansing and débridement (see “Débridement,” earlier), appropriate use of advanced dressings and procedures for dressing changes (see “Second-Intention Healing” later), and appropriate use of topical antimicrobial agents.

Antiseptic agents, in use since the 1800s, are effective against a broad range of gram-positive and gram-negative bacteria. However, they do not penetrate necrotic debris well and are unlikely to reduce bacterial populations deep in a wound bed. Many researchers have looked at the use of antiseptic and antimicrobial agents in the wound. In one study, the use of saline in combination with gauze was more effective in reducing bacterial numbers and encouraging wound healing than silver or povidone-iodine. In a review, Rodeheaver noted that the following antiseptics have been used in the false hope of killing bacteria without negatively affecting the wound bed: acetic acid, alcohol, aluminum salts, boric acid, chlorhexidine, formaldehyde, gentian violet, hexachlorophene, hydrogen peroxide, hypochlorite, iodine, povidone-iodine, Merthiolate, permanganate, and silver nitrate. It is clear that antiseptics should be reserved for use on the normal skin surrounding the wound, and not on the wound bed itself.

Unlike antiseptics, topical antimicrobial agents provide efficacy against bacteria within the wound bed, and, depending on the vehicle, they have minimal negative side effects on wound healing. In one study in horses with experimentally created leg wounds, silver sulfadiazine used alone without wound dressings resulted in less formation of granulation tissue than wounds covered with pressure bandages. Antiseptics cannot target specific bacteria, but topical antibiotics can. However, antimicrobial resistance has rendered some antimicrobials ineffective, so the use of systemic antibiotics alone has been advocated to control the appearance of resistant organisms. In some chronic infections, the blood supply to the surface is diminished, and topical antimicrobials are required. Antimicrobials should always be selected on the basis of culture and sensitivity or on the basis of a judgment about the most likely bacteria to be found in the wound. When possible, to reduce concerns about antibiotic resistance, the antimicrobial chosen for topical use should be one that is unlikely to be used systemically. Wound débridement is still the best way to reduce the bacterial count in wounds with necrotic debris, and it should be performed before either an antiseptic or a topical antimicrobial is used.

Systemic antibiotics should be used for chronic or acute wounds that have a large degree of trauma or are close to critical structures such as bones or joints. If possible, cultures and sensitivity test results should be obtained to determine an appropriate antibiotic. Triple antibiotic ointment has been shown to be one of the most effective topical antibiotics in wound healing. Nitrofurazone, at least in current vehicles, is quite toxic to wounds and cannot be recommended.

WOUND CLOSURE TECHNIQUES

After the wound has been successfully débrided, cleaned, and examined, it needs to be closed. The options are suture closure, healing by second intention, skin grafting, or some combination of these to provide a continuous epithelial surface over the wound. The type of closure technique to use depends on what caused the wound, the time from injury, the degree of contamination, the extent of the injury, and potential dead space. That there is a “golden period” of 6 hours from the wounding, after which the wound is considered to be infected, is no longer deemed correct, and it behooves the clinician to examine the wound carefully to determine which of the following techniques to use for wound closure.

Primary Closure

Primary closure is a technique whereby the wound is closed immediately and completely, using strict aseptic technique. This is the technique most likely to provide the best cosmetic result. Unfortunately, primary closure is acceptable only in wounds with minimal tissue loss, minimal bacterial contamination, and minimal tension on the wound edges after closure.

Regardless of whether primary closure or delayed primary closure (see later) is performed, the wound needs to be cleaned and prepared for closure, because excess bacteria in the wound increase the possibility of wound dehiscence. There are many suturing techniques for wound closure (see Chapter 17) and many reviews of suture types for primary closure. For areas of tension, complex suture patterns such as the near-far-near, vertical mattress, and horizontal mattress patterns provide more tension reduction than simple patterns such as a simple interrupted or simple continuous pattern. As it provides apposition of the skin edge at the same time as tension relief. Additionally, the mattress patterns can be used with stents to pull-through at the skin–suture interface. A large-diameter suture material should be used if tension exists. Small-diameter suture can be used between tension-relieving sutures for tissue apposition and cosmetic purposes. The wound edges should be undermined whenever possible, preserving blood supply, to reduce tension on the closed wound.

When closing a wound, the management of dead space is very important. Failure to obliterate dead space can lead to the development of a hematoma or a seroma, providing an excellent medium for bacterial growth. One or a combination of four techniques can be used to manage dead space in
a wound: suture, meshing, passive or active drains, and pressure bandages. Each technique has benefits and risks that need to be weighed. Suture material, although very useful in wound closure, can also act as a foreign body. Excess suture use (too much suture, too large a diameter, or too many knots) can potentiate infection. Consequently, the clinician much suture, too large a diameter, or too many knots) closure can also act as a foreign body. Excess suture use (too may suture, too large a diameter, or too many knots) can potentiate infection. Consequently, the clinician much suture, too large a diameter, or too many knots) closure, can also act as a foreign body. Excess suture use (too much suture, too large a diameter, or too many knots) can potentiate infection. Consequently, the clinician should use the smallest-diameter suture material possible, use monofilament, absorbable suture material, and use only surgeon’s knots (or interrupted sutures if absolutely necessary when the suture material must be buried). Good surgical technique also benefits the patient, as it reduces trauma to the wound site. If dead space cannot be managed by suture placement, meshing (see Chapter 24) or suction drains (passive or closed) should be employed (see Chapter 18). However, drains not only allow evacuation of dead space but can also act as a conduit for bacteria to enter the wound. Drains should be left in place only as long as necessary to reduce the possibility of infection. Pressure bandages can and should be used whenever possible in addition to sutures, meshing, or drains, or sometime in place of them to reduce dead space. A properly applied bandage closes dead space without adding any foreign material. However, if a bandage is too tight, the blood supply to the wound may be compromised, leading to wound failure.

**Delayed Primary Closure**

In a delayed primary closure, the wound is initially treated as an open wound to allow débridement and reduce bacterial contamination. Next, the wound is closed primarily. In some cases, only a portion of the wound can be completely closed (Fig. 26-10). Delayed primary closure is reserved for wounds that have mild to moderate bacterial contamination, minimal tissue loss, and minimal tension on the wound edges after closure. Drains may be placed to evacuate fluid after closure. Delayed wound closure is very useful in the management of abdominal incisions after colonic rupture in humans. These studies showed as much as a twofold increase in incisional infection with primary closure of contaminated abdominal wounds. Delayed primary closure after 3 to 5 days did not result in an increased hospital stay.

![Figure 26-10. A chronic wound that has been débrided and partially closed with near-far-far-near sutures.](image-url)

Wounds destined for delayed primary closure should be débrided and cleaned to reduce the bacterial burden. Hypertonic saline dressings (see “Second-Intention Healing,” next), topical antimicrobials, and systemic antimicrobials can be very useful in treating wounds prior to closure.

**Second-Intention Healing**

Second-intention healing occurs when primary or delayed primary closure cannot be accomplished. In most cases, these wounds have gross contamination and moderate to severe tissue loss that would make closure difficult. They must heal completely through the process of contraction, granulation, and epithelialization.

A relatively new concept in wound healing is moist wound healing, which occurs when the wound exudate is purposefully left in contact with the wound bed. In 1962, George Winter showed that in both swine and humans, full-thickness skin wounds kept in a moist environment reepithelialized in approximately 12 to 15 days, whereas similar wounds exposed to the air took 25 to 30 days to heal. Moist wound healing resulted in wounds that were less inflamed, caused less itching, had less eschar formation, and were more likely to heal without scarring. However, the earliest reports of moist wound healing were by Bloom and Bull in the mid 1940s. Bloom, an army surgeon, sterilized cellophane to treat burn wounds at a World War II prisoner of war camp. His primary goal was to reduce the risk of bacteria entering the wound. Although the dressing reduced bacterial infection, unanticipated benefits included movement with less pain, and less plasma loss. Bull and colleagues studied a transparent nylon that stopped bacterial and fluid penetration yet allowed wound exudate to escape from the dressing. Benefits included faster healing and fewer dressing changes.

The concept behind moist wound healing is that the wound exudate provides the necessary cells, and a substrate rich in enzymes, growth factors, and chemotactic factors controls infection and provides the best environment for healing. Enzymes come from the breakdown of white blood cells and metalloproteinases. Occlusive dressings keep the wound fluid in contact with the wound bed to encourage autolytic débridement. This in turn provides a good foundation for the rest of the wound healing process. Local growth factors and cytokines (see Chapter 5) provide a stimulus for the fibroblasts, epithelial cells, and angiogenesis. Chemotactic factors stimulate more neutrophils and macrophages for continued bacterial control and débridement. A moist environment allows better migration of neutrophils and macrophages than a dry wound environment. It has also been shown that wound fluid, even without white blood cells, has some antimicrobial action. Another benefit of occlusion is constant thermal regulation. Concerns with moist healing include bacterial colonization, folliculitis, and the possibility of trauma to periulcer borders. Although bacterial colonization is a concern, a wound that is not infected before occlusion is unlikely to become infected afterward. Another benefit of moist wound healing is that the reduced frequency of dressing changes means that the wound is less exposed to the environment, so it is less likely to become contaminated.
DRESSINGS, GROWTH FACTORS, AND DRUGS
The wound changes as it heals, and different dressings provide better results when used during specific stages of the healing process. Consequently, dressing manufacturers have developed many different dressings. Under the following headings, some of the more common dressings are described, and the wounds for which they are best used are mentioned. The ideal dressing keeps the wound bed moist, but not overly so, and the surrounding skin dry. The clinician needs to learn how to manage the amount of exudate present while making sure the wound does not dry out. Experience will quickly guide the use of the different dressing types. The dressings are described in the order a surgeon might use them when treating a wound.

Hypertonic Saline Dressing
Most wounds have necrotic tissue and need débridement. Hypertonic saline dressings (Curasalt, 20% hypertonic saline on a Kerlix gauze, Tyco Healthcare/Kendall) have been designed for use on necrotic or heavily exuding wounds. They work by osmotic action to remove necrotic tissue and bacteria (Fig. 26-11). They provide a nonselective chemical débridement and consequently need to be monitored carefully. Dressings need to be changed every 24 to 48 hours at the beginning of the treatment period to maintain the hypertonicity and thus the effectiveness. These dressings can be used effectively in most abscess situations. This dressing is available in a 6×6-inch loosely woven gauze with a 6-mm (¼-inch) cotton tape for packing small draining tracts. After the necrotic tissue or bacterial infection has been removed, another dressing type should be used.

Antimicrobial Dressings
Antimicrobial dressings have been designed to stop bacterial penetration. The agents are very effective against bacteria and minimally traumatic to the wound. I use a dressing called Kerlix AMD (Tyco Healthcare/Kendall) (Fig. 26-12). The active agent is polyhexamethylene biguanide (PHMB), and it is available bound to Kerlix Super Sponge, Kerlix roll gauze, and other types of dressings. PHMB belongs to a class of cationic surface-active agents that have been used as preservatives in aqueous solutions and as disinfectants and antiseptics (e.g., in cosmetics, contact lens solutions, baby wipes, and pool sanitizers). Increased concentrations, when impregnated into fabric, have shown the ability to suppress microbial growth and penetration. Microbial death occurs by destabilization and disruption of the cytoplasmic membrane, resulting in leakage of macromolecular components. This response is irreversible, and the microbe cannot adapt or become resistant to the PHMB. These dressings are particularly useful in preventing bacterial infection in surgical incisions or where wounds are close to synovial structures and subsequent deep penetration of bacteria would be catastrophic. Although the dressings have been designed to prevent bacterial penetration, they have also been useful in reducing the bacterial load in the wound (Fig. 26-13). As these dressings are dry, and made with woven gauze, they should be premoistened before being placed in a wound. They can also be used to cover surgically closed incisions. Silver has recently been impregnated into dressings as well, and they can be used in a similar fashion. The dressings should be changed every 3 to 7 days (the shorter times when used for open wounds, and the longer times for surgically closed wounds). After the wound has been cleared of infection, the dressing should be replaced with one of the following dressings.

Hydrogels
Hydrogel dressings were designed to provide moisture in a wound that has dried out. Hydrogels are medical-grade gels composed of water, glycerin, and polymers. They conform to the wound, are nondrying, and provide a bacterial barrier and eventually a moist environment. They are available as amorphous gels, in gel-impregnated gauze, or in a mesh-reinforced pad (Fig. 26-14). They are completely occlusive and provide an excellent environment for autolytic débridement, white blood cell migration, and thermal regulation, and they thus result in improved wound healing. The gel dressing should be changed every 4 to 7 days, depending on

Figure 26-11. Curasalt (Kendall/Tyco Healthcare), a 20% hypertonic saline dressing, 6×6-inch woven gauze, and packing tape.

Figure 26-12. Antimicrobial dressing, 6×6-inch woven gauze (a), and roll gauze (b).
the amount of exudate. Once the wound is moist, a different dressing should be used.

Calcium Alginate Dressings
Calcium alginate dressings are used primarily for the granulating phase of wound repair. They are made from alginate, a derivative of seaweed. The calcium in the dressing interacts with sodium in the wound, providing a wound exudate that stimulates myofibroblasts and epithelial cells and speeds wound homeostasis. The calcium also modulates epithelial cell proliferation and migration. Alginate dressings come in nonwoven pads and rope dressings. They conform well to the wound, have excellent vertical wicking properties, and are designed for moderately to heavily exudative wounds. If a wound has a granulation tissue defect and does not have a moderate amount of exudate, the pad should be premoistened with saline before use. The dressings can be changed every 3 to 7 days, depending on the amount of exudate.

Topical Dressings: Collagens, Maltodextrins
Topical dressings such as collagens and maltodextrins are designed for use in the granulating stage of wound repair. They are both hydrophilic and should maintain a moist wound bed. They are available in powder or gel form. If the wound does not have a lot of exudate, it is probably best to use the gel form to prevent drying out of the wound bed. Maltodextrins may provide nutrition to the wound bed. As soon as adequate granulation tissue is present, a semi-occlusive foam dressing should be used.

Biologic Dressings
Various substances have been used recently as biologic dressings. These dressings are intended to provide a framework over which other cells migrate, and as a stimulant to those cells to form the tissue that is desired. Some of the more commonly used biologic dressings include porcine small intestinal submucosa (SIS), porcine bladder basement membrane, equine amnion, and various skin products. The porcine small intestinal submucosa and bladder products are not rejected by the host as other xenografts are. From clinical experience, they appear to be best if they are kept moist. In a recent study, SIS dressing was applied to fresh and chronic wounds. Compared with similar wounds treated without SIS, exuberant granulation tissue was reduced and drainage was facilitated, which reduced wound exudation and improved epithelialization. Overall, wound healing was faster and costs for bandages and hospitalization were reduced. Other studies have shown that the use of equine amnion reduces wound retraction and granulation tissue formation while improving epithelialization. Amnion has been shown to be beneficial as a nonadherent dressing in skin grafting.

Growth Factors
Growth factors (see Chapter 5) have become very popular in experimental studies of wound care. The benefit of platelet-derived growth factor (PDGF) in decreasing wound-healing times has been shown. It acts as a chemotactic agent and mitogen for fibroblasts, smooth muscle cells, and inflammatory cells. Other growth factors have been studied in horses to determine their effects on granulation tissue formation. In one study, it was determined that transforming growth factor-β (TGF-β) has a profibrotic function in wound healing, in that it seems to encourage formation of granulation tissue. It was also found to be more upregulated in limb wounds than in trunk wounds. A human study has shown the benefit of leaving wound fluid in contact with the wound bed by stimulating fibroblast and endothelial cell growth. Various cytokines have been found useful in treatment of experimentally infected wounds. More studies need to be performed to look at different combinations of growth factors, used sequentially through the wound healing process to determine the true effectiveness of exogenous growth factors. The growth factors may be most useful...
in the granulating and epithelialization stages of wound healing and may be used in conjunction with other synthetic dressings.

**Semiocclusive Foam Dressings**

Semiocclusive foam dressings are designed for use on mildly exudative wounds (Fig. 26-15). They are best used after the wound has been cleaned up, necrotic debris has been removed, bacteria are brought to a count below that needed for infectivity, and healthy granulation tissue is present. The dressings should not be used in the presence of infection. Foam dressings provide a moist environment and thermal regulation that will enhance epithelialization while minimizing exuberant granulation tissue. It is best to surgically debride exuberant granulation tissue prior to application of a foam dressing. Foam dressings have also been useful as a nonadherent dressing in skin grafting. They should be changed every 4 to 7 days, depending on the amount of exudate.

**Corticosteroids**

Corticosteroids are commonly used in equine wound care to reduce the volume of, or to inhibit the formation of, exuberant granulation tissue. However, in vitro studies have shown that hydrocortisone upregulates plasminogen activator inhibitor-1 and downregulates plasminogen activators. The plasminogen activators play an important role in wound homeostasis. This change probably inhibits proteolytic matrix degradation and reepithelialization, which are both necessary for rapid and efficient wound repair. Dexamethasone has been shown to interfere with the synthesis and degradation of types I and III collagen in rats. Type III collagen plays a major role in the induction of wound healing and is affected more dramatically by dexamethasone. Triamcinolone has been shown to decrease wound healing and is affected more dramatically by dexamethasone. It is best to surgically debride exuberant granulation tissue prior to application of a foam dressing. Foam dressings have also been useful as a nonadherent dressing in skin grafting. They should be changed every 4 to 7 days, depending on the amount of exudate.

**Nonsteroidal Anti-inflammatory Agents**

Inflammation is an important part of the wound healing process. However, to achieve the most cosmetic and functional results, the inflammatory stage should be minimized. At therapeutic doses, studies have shown that there are few deleterious effects of using anti-inflammatory drugs during wound healing. In time, the selectivity of new antiprostaglandin drugs may provide better efficacy without potential side effects, which will make the use of these drugs even more beneficial.

**TETANUS PROPHYLAXIS**

Tetanus, caused by Clostridium tetani, should be prevented if at all possible. Adequate protection can be achieved by vaccination, but therapy after infection is often unrewarding. Although it has been shown that horses given an initial vaccination and a single booster should be protected for 5 years, it is probably better to have an annual booster. This is especially true in horses with an uncertain vaccination history. Unvaccinated horses should receive both a tetanus toxoid and a tetanus antitoxin.

**REFERENCES**

DEEP WOUNDS

Wounds in different parts of the body heal at different rates and often produce disparate cosmetic results. Wounds on the head, neck, and body often appear to heal better than wounds on the extremities. In a review on the topic, Knottenbelt discussed reduced vascularity in the extremities as a possible cause for prolonged wound healing there. However, increased infection, increased inflammatory response, and reduced regional temperature are all involved in the equation as well. The first part of this chapter is devoted to deeper wounds of the head, neck, thorax, abdomen, and extremities, and the second part discusses chronic wounds. Please see Chapters 5 and 26 for more in-depth information on specific wound healing events.

Head and Neck

The head and neck have an extensive vascular supply that provides nutrition, oxygen, and white blood cells to the wound for healing. There is good soft tissue support to most areas of the head and neck, which also provides a good basis for healing. Unfortunately, many other important structures, such as the cranium, eyes, ears, sinuses, salivary ducts, and nares, can be involved in lacerations, and exploring them to make sure that nothing is missed requires a thorough knowledge of their anatomy. For example, one horse had hit its head on a feeder, causing a laceration in front of the ear. At the initial presentation, the wound looked very superficial, but a more thorough examination revealed that it involved the cranium and had actually penetrated into the brain (Fig. 27-1). The horse had no obvious neurologic signs indicating the puncture. Thus, a thorough and complete physical examination is necessary to adequately assess wounds to the head and neck. Often, horses with head wounds should be heavily sedated before wound preparation and exploration.

Diagnostic aids for evaluating head and neck wounds include radiographs, ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI). Radiographs of the head can be difficult to evaluate because of all of the overlapping bones. CT (Fig. 27-2) and MRI provide excellent renderings of abnormalities, but they are expensive and not always available. Fortunately, good wound preparation and digital examination often provide enough information about the amount of bone involvement in a head laceration. Fractures should be considered whenever there is a laceration to the head. When cranial fractures are suspected, a thorough neurologic examination should be performed to help determine the extent of the laceration. If the cranium is involved, aggressive therapy should be instituted to reduce the possibility of bacterial penetration and eventual septic encephalitis.

Lacerations around the orbit should be examined to determine involvement of the bone and the globe of the eye (see Chapter 63). To avoid trauma to the cornea, special care is needed when cleaning around the eye. Chlorhexidine should not be used in this area. If possible, lacerations around the eye should be closed primarily to reduce functional problems of the lids. Lacerations to the lids should be closed using small-diameter, absorbable suture material in
many layers (see Chapter 56). Multiple layers of small-diameter suture provide more stability in areas of increased motion yet will not unnecessarily add to the foreign body volume of the wound. Orbit fractures can be treated using bone reconstruction plates (Fig. 27-3).

Repair of ear lacerations can be particularly difficult because ears have considerable mobility. Their range of motion is nearly 270 degrees, and they are supported by cartilage. Ear lacerations, like eyelid lacerations, should be closed primarily whenever possible for the best cosmetic and functional results. Because of the location and blood supply of the ear, lacerations there are rarely too contaminated to close primarily, but sometimes the wounds are too old to hold suture and must heal by second intention, with revision at a later date. General anesthesia should be used to repair ear lacerations for the best cosmetic result. Rolled gauze or radiographic film can be used as a support to minimize ear movement and improve healing.

Lacerations that involve the frontal and maxillary sinuses may lead to bone sequestration and eventual fistula formation. Prompt intervention can make the difference between a wound that can be closed primarily and one that requires multiple surgeries and wound revisions. Stable bone fragments should be elevated back into position, whereas loose fragments devoid of periosteal coverage should be removed. Rotational skin and periosteal flaps may be necessary to close defects in this area. If there is a large bone defect, the addition of a periosteal flap may improve the possibility of bone formation in the area. Other dressings, such as ACell (ACell, Inc, Jessup, Md), have been suggested for use in this type of wound to encourage bone formation.

Mandibular lacerations can involve other structures such as the salivary ducts or even the mandibular incisors. Depending on the cause of the laceration, evaluation of the ducts can be very difficult, especially if extensive trauma has occurred. When possible, the integrity of the duct should be confirmed by feeding the horse and observing salivary fluid loss. If transected ends of the parotid salivary duct can be visualized and anastomosed, the result will be better, but this is rarely achievable. If the ends cannot be anastomosed, the salivary gland may have to be chemically ablated.

Lacerations of the nares are common in equine practice. Successful reconstruction depends on thorough wound debridement, good case selection, and using multiple layers of suture closure to reduce the chance of incisional dehiscence. Fresh wounds are easiest to treat if there is not a large volume of tissue missing. When horses present with wounds that are 7 to 20 days old, the wounds should probably be allowed to heal by second intention and reconstructed at a later date when they are more likely to hold sutures. In all cases of nares lacerations, multiple layers of closure are necessary for a successful closure.

Thorax

Lacerations of the thorax can involve the ribs, which can penetrate the pleural cavity and cause a pneumothorax. Consequently, the wounds must be carefully examined to be absolutely certain of the depth of penetration. The area should be clipped and aseptically prepared to allow a thorough examination of the site (see Chapter 26) Aseptic technique should be used for all thoracic wounds, as involvement of the pleura cannot be ruled out until after the manual examination. If the examination area is quiet, the surgeon may be able to hear air being sucked into the wound during inspiration. Thoracic auscultation should also be performed to help rule out pneumothorax. Radiographs and ultrasonography can be helpful adjuncts to the examination (Fig. 27-4). If the wound has entered the pleural cavity, a chest tube should be placed to evacuate the air from the chest (see Chapter 18). If the surgeon cannot place a chest tube, the wound should be closed in as many layers as possible, bandaged, and then referred (see Chapters 8 and 47). As an alternative to a chest tube, a teat cannula can be attached to a 60-mL syringe with a three-way stopcock to remove air from the chest cavity. With time, it is

Figure 27-3. Intraoperative photograph of a horse with an orbital fracture repaired with a reconstruction plate.

Figure 27-4. Lateral radiographic view of a horse with a thoracic injury and subsequent pneumothorax. Note the dorsal edge of lung outlined by arrows.
possible to evacuate most of the air from the pleural cavity with this technique, but a suction pump is more efficient. The chest tube or the teat cannula should be placed in the upper third of the chest to enable removal of the largest volume of air. When there is pleural penetration, broad-spectrum antibiotics should be instituted. The wound care instituted should be appropriate for the stage of healing. Stent bandages can be used to cover the primary dressing.

**Abdomen**

Lacerations to the abdominal wall offer a diagnostic challenge. The abdominal wall has numerous layers that vary depending on the location. The hair should be clipped, and aseptic technique should always be used on abdominal wounds until peritoneal penetration has been ruled out. If the entry point is small, it may be useful to enlarge the wound to better explore the deeper layers, and the horse may have to be sedated to allow thorough examination. The skin is generally more resistant to tearing than the fascial planes and muscles of the abdominal wall. All tissue planes should be examined for involvement. It is possible for the tissue planes to move, allowing overlap of the layers. An abdominocentesis may help, but in many cases, the cell counts and total protein are not abnormal. Confirmation of abdominal penetration may not be possible, so the veterinarian must carefully monitor the patient for signs of peritonitis after the wounding.

If the wound does not involve the peritoneal space, it should be débrided and closed in multiple layers if at all possible. A drain may be helpful in evacuating dead space. Wounds that have a large amount of tissue loss may be predisposed to herniation. However, it is not advisable to place a mesh in a contaminated wound. Therefore, the wound should be treated until healed, and then a mesh can be placed to reduce the chance of hernia formation. Abdominal bandages can be useful to help support the body wall. The need for abdominal support may be minimal, but the bandage often reduces edema formation at the wound site and encourages more rapid wound healing. Broad-spectrum antibiotics are often indicated in abdominal wounds.

If peritoneal penetration has occurred, an abdominal bandage should be placed on the animal for transport to a surgical facility for an abdominal exploration. Whenever peritoneal penetration has occurred, it is possible that there has been trauma to the viscera. Abdominal lavage using copious amounts of polyionic fluid should be performed, and broad-spectrum antibiotics should be instituted.

**Extremities**

**Axillary Lacerations**

Horses that present with lacerations of the axillary region often have subcutaneous emphysema (Fig. 27-5). The emphysema is created when the horse moves its leg forward,
opening the wound and filling it with air. When the horse moves forward and the leg becomes caudal relative to its forward position, the air is trapped and forced into the surrounding tissues. In some cases, a pneumomediastinum occurs, which can lead to a pneumothorax. The hair over these wounds should be clipped, and they should be cleaned and débrided. Packing the wound is difficult, but it reduces the accumulation of air. The best way to reduce subcutaneous air accumulation is to limit the movement of the horse. Once the air has accumulated, it must be reabsorbed, and there is no efficient way to remove it. Calcium alginate dressings may encourage formation of granulation tissue, speeding the sealing of the wound.

Lacerations Involving Synovial Structures

Lacerations into synovial structures must be identified and aggressively treated as early as possible. The veterinarian must know the locations of the synovial structures—repeated and thorough reviews of equine anatomy are helpful. Whenever a laceration occurs that is close to one of these structures, synovial involvement must be determined. The best way to confirm the involvement of a synovial structure is to place a needle into the structure at a site distant from the wound and distend the structure with sterile saline (Fig. 27-6). Strict aseptic technique is a prerequisite for this injection. If the wound involves a synovial structure, aggressive therapy, including lavage, intravenous antibiotics, local perfusion, and effective wound dressings, should be performed (see Chapters 8 and 88).

Heel Bulb Lacerations

Lacerations to the heel bulb area are common in equine practice and can involve anything from the skin to the coffin joint, so the structures involved must be identified. Synovial involvement of either the digital flexor tendon sheath or the coffin joint should be ruled out before treatment. If there is no synovial involvement, heel bulb lacerations are often best repaired using delayed primary closure. Because the foot is in contact with the ground, most heel bulb lacerations are very contaminated. Effective wound preparation, débridement, and treatment are critical (see Chapter 26). After the wound is cleaned, it can be sutured and a slipper cast applied. The slipper cast reduces movement in the area and allows much more rapid and cosmetic healing (Fig. 27-7). Additional information of the management of heel bulb wounds is found in Chapter 93.

CHRONIC WOUNDS

Chronic wound care can be challenging and demanding. In human medicine, “a chronic wound is a window to underlying disease. Each wound is a symptom of underlying infirmities that undermine the potential for healing.” The local wound environment is part of the larger milieu of the body, and chronic, nonhealing wounds can indicate a larger problem in the macroenvironment of the body. Consequently, it is critical to examine the entire animal when a nonhealing or chronic wound is present. Chronic wounds in both people and horses are commonly found on the extremities. In people, they are often secondary to chronic metabolic diseases, whereas horses often have some type of underlying infection.

Much work has been done on the local wound environment of nonhealing wounds in humans. Studies have shown that wound fluid found in chronic wounds inhibits the growth of fibroblasts by affecting the cell cycle. The negative effect of the wound fluid can be reversed by high temperatures. Tumor necrosis factor-α (TNF-α) may play a
role in the reduction of fibroblast growth rates, whereas interleukin-1β (IL-1β) and transforming growth factor-β1 (TGF-β1) did not significantly affect growth rates. Other studies have shown an increase in fibroblast proliferation when these cells are exposed to wound fluid from chronic wounds. Differences in experimental conditions may have caused the difference in results, which underscores the importance of further research into the effects of chronic wound fluid.

Another difference in wound fluid obtained from acute versus chronic wounds is in proteolytic activity. In acute wound fluids, the plasminogen activator system is active, and in chronic wound fluids, the urokinase-type plasminogen activator and urokinase-type plasminogen activator receptors are active. Different proteins are expressed at different levels during the wound healing process. Heat shock protein, platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), vascular endothelial growth factor (VEGF), and their receptors were increased in the wound within 24 hours of skin injury. The levels declined to normal levels by day 7 to day 14, coinciding with healing. The expression of these factors in chronic wounds was delayed or inhibited, suggesting that addition of these agents might improve wound healing in chronic wounds.

Sarcoids are the most common cutaneous tumor in the horse. It is not uncommon for sarcoids to occur at the location of previous wounds. A study designed to look at the response of cells—isolated from sarcoids, granulation tissue, and normal dermal fibroblasts grown from primary cell cultures—to growth factors showed different morphologic features for each cell type. Sarcoi-derived and granulation tissue-derived cells grew more slowly than the normal dermal cells. When growth factors (epidermal growth factor, acidic fibroblast growth factor, and basic fibroblast growth factor) were added, the sarcoi-derived cells and normal cells were stimulated, but the granulation tissue-derived cells were inhibited. However, when TGF-β was added, the granulation tissue-derived cells were not preferentially inhibited. Continued research in wound healing should help to identify ways to change chronic wounds to acute wounds, thereby improving the healing response.

Chronic wounds often heal with a poor functional and cosmetic result. For the most functional and cosmetic healing, the best environment for wound healing should be provided early. The best way to treat a chronic wound is to not allow the wound to become chronic in the first place. As this is not always possible, the surgeon is required to treat horses with chronic, nonhealing wounds.

As with an acute wound, the first step in treating a chronic wound is to prepare the wound for examination (see Chapter 26). The examination generally starts with digital exploration. The wound should be explored for pieces of foreign material (e.g., bone, wood, metal, suture material). In some cases, draining tracts are found that guide the exploration (see Chapter 28). In others, the foreign material is walled off and difficult to palpate. In those cases, ancillary methods such as radiology, ultrasonography, CT, or MRI can be useful. Radiographs are best for bone and other radiodense objects. Ultrasonography can be very useful for radiolucent objects such as wood. CT and MRI may be very useful but are often cost prohibitive.

Infection should be suspected whenever a wound does not heal in the anticipated timeframe. In a review of wound infection, Dow identified studies that show the effect of chronic wound infection on wound healing. He also identified the best ways to diagnose wound infection, the most common being by the clinical appearance of the wound. Inflammation, edematous granulation tissue, discolored granulation tissue, draining tracts in the granulation tissue, and odor are clinical signs that should increase suspicion of infection (Fig. 27-8).
A second (and the absolute) way to determine infection in a wound is by bacterial culture. However, all wounds contain bacteria. A wound with a bacterial burden of $10^7$ or $10^8$ bacteria per gram of tissue is generally considered to be infected. Quantitative bacteriology involves submitting a defined amount of tissue (at least a gram) for bacterial culture and calculating the number of bacteria per gram of tissue. This is rarely done in equine medicine, but it should be considered when wound healing does not progress as expected. Qualitative culture should be done to determine the types of bacteria in the wound, and antibiotic sensitivity testing should be performed to determine the most effective antibiotic. (See Chapter 26 for information on topical antibiotics, antiseptics, and systemic antibiotic therapy.) The most important step in reducing wound infection is adequate débridement and removal of foreign material.

After examining and exploring the wound, the surgeon decides the next step in wound care. In many cases, the wound needs to be "freshened" to stimulate it to heal. Surgical débridement, commonly used to accomplish this (Fig. 27-9), can essentially turn a chronic wound into an acute wound. It generally reduces the bacterial load and removes foreign material. Surgical débridement is a vital adjunct for wound care in humans with diabetic foot ulcers, and it is an important part of chronic wound therapy. Any infected bone or tissue should be removed by the débridement, so that no foreign material is left behind.

As previously described, growth factors hold promise for wound healing. An understanding of the wound environment is necessary before growth factors are routinely used. Purified growth factors may be useful only in combination. After surgical débridement, wound closure may be attempted (see Chapter 26). A benefit of working with a chronic wound is that the granulation and scar tissue often stretch the skin. After the scar tissue and granulation tissue are removed, there is ample skin to close the defect. In some cases, only a portion of the wound can be closed, and the rest is allowed to heal by second intention or skin grafting (see Fig. 26-10). The skin within approximately 1 cm of the skin edge is usually not healthy enough to hold sutures, and it is often best to remove this tissue during wound débridement.

Sometimes, wounds do not respond in an anticipated fashion, and keloids or excess scar tissue results. Keloids are distinguished from hypertrophic scars in that keloids extend beyond the original wound and rarely regress. The pathogenesis of keloid or hypertrophic scar formation is unknown, but it has been linked to an increased number of epidermal Langerhans’ cells. The epidermal immune barrier may play an important role in the development of hypertrophic scars, which have been noted to have increased blood flow in humans evaluated with laser Doppler. In the normal wound healing process, the vasculature diminishes, allowing the completion of healing. Hypertrophic scars may represent an interruption in this healing process. Possibly, vasoconstrictive agents employed in the maturation stage of healing would reduce the proliferation of vasculature, which might inhibit hypertrophic scarring. In humans, there is a familial disposition to keloids, and steroid injection, surgical excision, radiation therapy, compression, and tension reduction have been used for treatment of keloids. In vitro culturing of fibroblasts from keloids with the dietary compound quercetin (a flavonol) has shown some promise in inhibiting proliferation and contraction of the cells.

SINUS TRACTS AND FISTULAS

Sinus tracts are distinct from fistulas, although the terms are often used interchangeably. A fistula is an abnormal passage or communication, usually between two internal organs or leading from an organ to the surface of the body. Examples include communications between a tendon sheath and a joint (synovial fistula), from the intestine through the abdominal wall (enterocutaneous fistula), and between the mouth or esophagus and the surface of the body (orocutaneous or esophageal fistula). A sinus tract, on the other hand, is defined as a cavity or channel, and it may be normal (e.g., a venous sinus), or it may be a pathologic condition (e.g., an abnormal channel or fistula that permits the escape of pus through the skin). In this chapter, the discussion is limited to the management of sinus tracts. Fistulas are described in chapters dealing with the specific affected anatomic organ or space.

ETIOLOGY

Chronic sinus tracts in horses commonly occur secondary to trauma and foreign bodies. Those involving the lower limbs are frequently associated with bone sequestra (Fig. 28-1). Many of these become self-limiting, as the sequestrum undergoes natural debridement or will resolve immediately after sequestrectomy. However, chronic sinus tracts associated with foreign bodies have been described in many areas of the body and are sometimes quite difficult to resolve, especially if the foreign body is inert and not easily degraded by lysosomal enzymes released from white blood cells. Foreign bodies can be wood, metal, and even plastic. Frequently, nonresorbable suture material results in a chronic sinus tract.
Sinus tracts are distinct from fistulas, although the terms are often used interchangeably. A fistula is an abnormal passage or communication, usually between two internal organs or leading from an organ to the surface of the body. Examples include communications between a tendon sheath and a joint (synovial fistula), from the intestine through the abdominal wall (enterocutaneous fistula), and between the mouth or esophagus and the surface of the body (orocutaneous or esophageal fistula). A sinus tract, on the other hand, is defined as a cavity or channel, and it may be a pathologic condition (e.g., an abnormal channel or fistula that permits the escape of pus through the skin). In this chapter, the discussion is limited to the management of sinus tracts. Fistulas are described in chapters dealing with the specific affected anatomic organ or space.

**ETIOLOGY**

Chronic sinus tracts in horses commonly occur secondary to trauma and foreign bodies. Those involving the lower limbs are frequently associated with bone sequestra (Fig. 28-1).

Many of these become self-limiting, as the sequestrum undergoes natural debridement or will resolve immediately after sequestrectomy. However, chronic sinus tracts associated with foreign bodies have been described in many areas of the body and are sometimes quite difficult to resolve, especially if the foreign body is inert and not easily degraded by lysosomal enzymes released from white blood cells. Foreign bodies can be wood, metal, and even plastic. Frequently, nonresorbable suture material results in a chronic sinus tract.
Sharp foreign bodies have a tendency to travel, especially when one end is blunt and the other is sharp, and can be found at some distance from the original site of entry. Examples of this include wood and metal foreign bodies with one blunt and one pointed end and even surgical instruments (Fig. 28-2).

**DIAGNOSIS**

Because foreign bodies are suspected at any time a chronic sinus tract is encountered, identification of the type of foreign body prior to surgery is always attempted. Foreign bodies are frequently noted as radiographic abnormalities on survey films, and, therefore, survey films should always be taken. Metallic foreign bodies are easily diagnosed this way. Other abnormalities include soft tissue swelling, thickening, gas densities, and soft tissue and periosteal reactions near bone, any of which may allow the foreign material to be located and identified.

Positive-contrast sinography is easily performed with water-soluble contrast medium (Fig. 28-3). It is particularly useful for identification of radiolucent foreign bodies, which frequently appear as space-occupying lesions in the center of the contrast material. Ultrasonography is also useful in the diagnosis of foreign bodies such as wood, especially those embedded in muscle. Water-bath studies have shown that bone, wood, and large tendons all demonstrated acoustical shadowing in equine muscle. Differences in hyperechogenicity and acoustical shadows help detect and identify a foreign body.

**EXPLORATION**

Extrirpation of the foreign body is the treatment of choice for a chronic sinus tract. Exploration of the sinus is carried out with a malleable probe and a groove director (Fig. 28-4). A malleable probe is used to determine the direction in which the exploration should occur (Fig. 28-5), and a groove director allows sharp dissection of the superficial portion of the sinus tract, which can be opened rapidly without bypassing the tract. Frequently, sinus tracts travel at varying angles and need to be opened in several directions. Occasionally, they even need to be opened a fair distance from the opening in the skin.

After exploration with a malleable probe, the groove director is inserted through the opening in the skin and guided along the probe. The probe is removed, and with the point of a no. 10 scalpel blade placed in the groove, the tract is opened toward the skin (Fig. 28-6). This process is repeated if the tracts continue in other directions. When sinus tracts are quite deep, Weitlaner retractors are useful to hold open the incision. The tract itself usually has a dark purple membrane, which allows easy identification. Initial infusion of a vital dye such as Evan’s blue further facilitates recognition of the tract during surgery, as it stains the tract lining dark blue.

After the foreign body has been identified and removed, all linings of the sinus tract should be curetted so that most of the bacterial contamination is removed and the sinus
tract will stop draining. The membrane itself will produce purulent material for some time. The tract should be thoroughly flushed with sterile saline. Although much of the tract may be closed after this procedure, it is usually better to simply débride the cloaca rather than to close it.

**SPECIAL CONSIDERATIONS**

The location of the sinus tract may be an indication that the tract did not develop secondary to a foreign body. Any time a sinus tract develops on the head, a sinus infection or a dental problem should be suspected, especially if sinography outlines the tract to the apex of a tooth. A sinus tract opening found near the base of the ear is usually the result of a conchal cyst ("ear tooth"). This can easily be diagnosed with radiography (Fig. 28-7). (For details on surgical treatment of this condition, see Chapter 29.) A sinus tract over the pole or the withers region may indicate the development of an infected bursa in this area (Fig. 28-8). The former is called pole evil and the latter is called fistulous withers. If either is the case, a blood sample should be taken to determine a *Brucella* titer, as brucellosis is a human health hazard.

**COMPLICATIONS**

Lacerations or incisions into large vessels, or even into internal organs, are possible when following a sinus tract. Therefore, caution is necessary when sinus tracts are deeply embedded in and around body cavities. Also, some sinus tracts may contain more than one foreign body, especially if the foreign body is made of wood or nonabsorbable suture material. Owners should be warned that recurrence is a possibility any time this exploration is attempted, and that, in fact, foreign bodies sometimes cannot be found. Another surgery may be necessary when a new cloaca forms from a new sinus tract.
REFERENCES

Figure 28-7. Sinus tracts located at the base of the ear usually indicate the presence of a conchal cyst. This can usually be palpated just cranial to the ear as an enlargement (A), radiographs confirm that it is a tooth (B), and the aberrant tooth with its cyst lining is removed in its entirety (C).

Figure 28-8. Any time a sinus tract develops along the withers, the condition of fistulous withers is suspected, and this can be confirmed with radiographs. However, because this may be a zoonosis involving infection with Brucella, cultures and a titer should be obtained prior to further diagnostic workup and treatment.
CHAPTER 29

Skin Conditions Amenable to Surgery
Elizabeth A. Carr

The vast majority of equine skin diseases requiring a surgical consultation or surgical intervention are neoplastic in origin. Consequently, the major focus of this chapter is on neoplasms of the skin. The biologic behavior, predisposing factors, diagnosis, prognosis, and treatment options are discussed. When available, comparative reviews of treatment protocols are included. The goal of this chapter is to provide information to assist the clinician in determining the best approach to treatment of a particular neoplastic condition. In addition, a handful of other skin conditions are reviewed. This is not an exhaustive review of all skin conditions but instead a review of the more common diseases, with an emphasis on those that are amenable to surgical resolution.

SARCOIDS

The equine sarcoid was first described by Jackson in 1936.¹ The most common tumor in horses worldwide, sarcoid is a cutaneous, fibroblastic neoplasia with a proliferative epithelial component.¹ Sarcoïds are frequently classified histopathologically as benign tumors because of the morphologic characteristics of the fibroblasts and because many sarcoïds are slow growing and cause little if any physical problems in the affected animal. This classification is misleading, however, and ignores the large number of tumors whose clinical behavior can only be described as malignant.²

Sarcoïds are subtyped, on the basis of clinical appearance, into occult, verrucous, nodular fibroblastic, ulcerative fibroblastic, mixed tumors, and malevolent. This classification correlates with their biologic behavior (Fig. 29-1). The most aggressive subtype consists of malevolent sarcoïds, which infiltrate locally along fascial planes and vessels; grow rapidly, and have a high recurrence rate after excision.³

Sites of predilection vary with geographic location and include the face (muzzle, ears, and periocular region), distal limbs, neck or ventral abdomen, and areas of previous injury and scarring.³ Location has been reported to affect prognosis, with sarcoïds on the distal limb and periorbital region having a worse prognosis for resolution than sarcoïds in other locations.

Epidemiology

The relationship between breed and risk for development of sarcoïd was evaluated in a large number of horses admitted to the New York State College of Veterinary Medicine between 1975 and 1987.⁴ Quarter Horses and related stock breeds were almost twice as likely to develop sarcoïd as Thoroughbreds. Standardbred horses were less than half as likely to develop sarcoïd as Thoroughbred horses. A direct genetic linkage has been reported between equine leukocyte antigens (ELA) and risk for equine sarcoïd. ELA alleles A3 and W13 were strongly associated with risk for sarcoïds in Thoroughbreds and Swiss, French, and Irish Warmblood horses.⁵,⁷ The absence of the W13 allele in the Standardbred population may confer relative resistance to sarcoïds. Interestingly, a familial predisposition has been reported in a herd in which all five descendants of a sarcoïd-affected mare developed sarcoïd, whereas none of the unrelated animals on the premises developed these tumors.⁸

Spontaneous malignancies that develop as a result of serial genetic mutations are more common in older animals. Sarcoïds generally develop in younger individuals, suggesting a genetic predisposition or an exogenous factor. Individuals with a genetic predisposition have an inherited gene defect that increases their susceptibility to further mutation. Consequently, these individuals develop tumors at a much earlier age. The genetic predisposition for and the age of onset of sarcoïds suggest that both genetic factors and exogenous factors may play a role in development. A long-term epidemiologic study of a large herd of donkeys suggests the possibility of transmission of sarcoïds between individuals housed in close contact.⁹ In addition, an epizootic outbreak was reported in a small herd.² Incidence peaked in young horses over a 1-year period. Interestingly, only related, highly inbred animals were affected. A vector such as a fly may explain the predisposition for tumors to develop around the eye, distal limbs, and ventrum (common feeding locations for these insects).

A specific viral etiology was first proposed by Olsen and Cook.¹⁰ While studying the transmissibility of cutaneous papillomas, they noted a striking similarity between equine sarcoïd and experimental lesions induced by the injection of bovine wart extracts into the skin of individual horses. Several research groups have since confirmed the presence of bovine papillomavirus (BPV) DNA in nearly all equine sarcoïd tissues examined.¹¹-²⁰ Papillomaviruses play a role in oncogenic transformation in other species, but viral infection alone is not enough to trigger transformation, as BPV DNA can be found in normal skin of sarcoïd-affected horses.²¹ Papillomavirus infection of an abnormal host (such as BPV infection in a horse) generally results in a nonproductive infection; consequently, no viral capsids are produced. Instead, the virus maintains its presence by production of several housekeeping genes, including two, E5 and E6, known to be capable of transforming cells to malignancy. The production of one of these two transforming genes, E5, has been documented in a small number of sarcoïds examined.²² Expression of the viral E5 protein appeared to correlate with the grade of tumor malignancy. Furthermore, although viral DNA was detected in normal skin surrounding sarcoïds, E5 protein expression was not. A triggering event such as trauma may be required to activate a latent viral state. This could be one explanation for the tendency for sarcoïds to occur at the sites of previous injuries. Experimental inoculation of purified viral DNA has resulted in sarcoïd-like tumors, but the majority of these lesions regress spontaneously.²³
A viral role is strongly suggested by the finding of viral DNA and viral transforming proteins in all sarcoids examined. However, the mechanism of viral transformation is unclear. Given the genetic and breed predispositions, sarcoid occurrence is most likely the result of host, viral, and environmental factors.

**Treatment**

There are numerous articles regarding treatment of sarcoids. The number of treatment options reflects the variable success as well as the costs of certain treatments. Efficacy is difficult to critically assess; most early studies were not controlled and were based on a subset of cases sent to referral hospitals. Sarcoïds commonly referred for treatment are usually more aggressive variants or tumors that have recurred after unsuccessful treatment. Sarcoïds can transform to a more aggressive phenotype after incomplete or unsuccessful treatment and are then harder to resolve. In contrast to those tumors typically seen at referral centers, there is anecdotal evidence of a subset of sarcoïds that remain quiescent and of others that undergo spontaneous regression.

**Figure 29-1.** Subtypes of sarcoids. **A,** A verrucous sarcoid on the temporal region of the head. **B,** A subcutaneous fibroblastic sarcoid. **C,** An ulcerative fibroblastic sarcoid. **D,** A mixed form consisting of both verrucous and fibroblastic components. **E,** A horse with a malevolent sarcoid. The lesion had spread down the neck along lymphatic chains, and to the retropharyngeal and parotid lymph nodes.
Surgical Excision

Surgical excision without adjunctive therapy has been reported to be one of the least successful treatment options, having a recurrence rate of 15.8% to 82%. The reason for this may in part be that tumor projects fronds of malignant cells into the surrounding "normal tissue." Because these projections are infrequent, they are missed on histopathologic review, leading to an incorrect assumption of complete excision. In addition, the possibility exists that a viral agent may remain latent in the surrounding tissue. Surgical trauma and the subsequent growth stimulation may trigger viral activation and expression of viral oncogenes. In a recent prospective trial, the detection of viral DNA at the surgical margin of an excised sarcoïd correlated with an increased risk of recurrence.

Laser Ablation

Laser ablation of tumors has been used to remove or debulk tumor mass. Laser ablation causes less damage to the surrounding tissues and less spread of malignant cells to healthy regions than sharp surgical excision with mechanical tools. A large retrospective study evaluating CO2 laser excision of 60 sarcoïds documented an overall recurrence rate of 38%. The use of laser ablation in conjunction with intralesional chemotherapy or other adjunctive therapy may improve overall success rates.

Cryotherapy

Cryotherapy (see Chapter 15) has historically been one of the most commonly used methods for treatment of equine sarcoïd. Success rates of 60% to 100% have been reported. However, a recent retrospective study evaluating treatment success in a large number of periorbital sarcoïds reported a recurrence rate of 91% (9% success rate) in tumors treated by cryotherapy. Longer follow-up time may explain the discrepancy in successful outcome. Cryotherapy has its greatest success with veterinarians who use it frequently and have experience with duration and depth of freeze, which are important for an effective response. Thermocouples can be utilized for more precise measurement of the tissue temperature and depth of freeze. In one report, the use of a three-treatment, −30°C protocol was felt to be more effective than a two-treatment −20°C protocol, with an overall initial success rate of 68%. With multiple repeat treatments, the success rate improved to 85% (85 tumors resolved of 100 retreated). Thirty-three of the 50 horses were cured of their sarcoïds using a liquid nitrogen spray apparatus, although many required multiple treatments. Three horses in this study had spontaneous regression of untreated tumors after cryotherapy of another lesion. This seems to indicate that destruction of one tumor can result in an immune response against another, distant sarcoïd.

Hyperthermia

Hyperthermia has been reported to be successful in a small number of equine sarcoïds, with spontaneous resolution of some of the nontreated tumors. Differences in the metabolic rate of tumor cells compared with normal cells is thought to make the tumor cell more heat sensitive.

Radiotherapy

Radiotherapy using locally implanted iridium-192 has been reported to be successful in the treatment of sarcoïds. The recurrence rate was low, with 1-year tumor-free incidences of 94%, 87.5%, and 100%. Radiotherapy using a linear source of iridium-192 has been reported to have a 100% success rate in a small number of sarcoïds. All cases were reported to resolve after a single dose of radiation. Recurrence rate at 1 year was zero for all tumor types, but the number of cases actually followed for a full year was not reported. The 1-year progression-free survival was 86.6% in 62 sarcoïds treated with iridium interstitial brachytherapy. Treatment complications included hair and pigment loss as well as fibrosis, cataract formation, and corneal ulceration when treating periorcular tumors. Radioactive gold-198 implants have been reported to have a high success rate for treatment of sarcoïds—a rate similar to that for the other implant therapies. Although reported success rates using radiation therapy are high, treatment is expensive, requires special equipment and housing, and is potentially hazardous. General anesthesia may be required to implant iridium needles or to deliver a radiation dose via a linear source. These limitations make radiation therapy a difficult and infrequently utilized method of treatment and confine its use to referral centers.

Immunotherapy

Immunotherapy has been used to successfully treat sarcoïds in several reports. Several immunostimulants have been utilized, including Mycobacterium cell wall extracts, live whole-cell bacille Calmette-Guérin (BCG), and propionibacterial cell wall extracts. These products are thought to stimulate cell-mediated immunity, leading to recognition of tumor cell–specific antigens and subsequently to tumor cell destruction. Most immune stimulants require multiple intralesional injections with or without prior cytoreduction of the tumor mass. Success rates are high for smaller tumors, tumors located periorbitally, and fibroblastic tumors. Knottenbelt and Kelly reported a poorer success rate with occult or verrucous periorbital lesions and hypothesized that this was because of the inability to saturate the tumor bed effectively. Multiple treatments are generally required. Local tissue swelling can be quite severe, and complications include death from anaphylactic shock, particularly after two or more injections. Spontaneous regression of untreated tumors has also been reported with immunotherapy. Recurrence rates vary from 0% to 40%, depending on the study and observation time.

Intralesional Cisplatin

Intralesional cisplatin in an oily emulsion is reported to have an 87% 1-year relapse-free rate for sarcoïds. The repositol effect of the oily emulsion prevents significant systemic levels, avoiding systemic toxicity, and maintains effective tissue levels of the chemotherapeutic for prolonged periods of time. Epinephrine can be added to the emulsion (1:1000, diluted 1:10). The resultant vasoconstriction prolongs tumor cell exposure to cisplatin. A dosage of 1 mg cisplatin per cubic centimeter of tumor mass, with a minimum of four treatments, is recommended. Cytoreduction to

INTEGUMENTARY SYSTEM

decrease the mass of the tumor is beneficial when treating large tumors. Intralesional cisplatin instituted at the time of surgical excision or debulking was not shown to affect wound healing. The repo sitol effect of the oily emulsion is critical for treatment success. A 66% recurrence rate after cisplatin treatment was reported by Kno ttenbelt. However, the concentration used was lower than that recommended by the original authors.

Intralesional tumor necrosis factor (TNF) combined with a xanthate compound has also been used with success.

Topical Application of Chemotherapeutics

Topical application of chemotherapeutic agents, including 5-fluorouracil (5-FU) and a series of compounded creams, have been reported to be successful in the resolution of sarcoids. 5-FU had a resolution rate of 66% in nine tumors treated daily for 15 days, but only small occult or verrucous sarco ids were chosen for this treatment protocol. In the same report, the AW4-LUDES cream had a resolution rate of 35% (56 of 146 tumors treated) without complication. The authors reserved this treatment for small, previously untreated verrucous lesions. Six additional tumors resolved with the topical application of AW4-LUDES but had significant scarring after treatment. As with 5-FU, the authors recommend avoiding the use of these creams on tumors in close proximity to the eye. Topical application of a compounded cream containing bloodroot and zinc is anecdotally reported to be extremely effective in the treatment of equine sarcoid, but few controlled studies have been done. I evaluated one sarcoid-affected horse that was treated with this compound; in response to the compound, the tumor became very swollen and ulcerated and began to grow rapidly. More controlled studies evaluating the efficacy of bloodroot and zinc against different types of sarcoid tumors are needed.

Spontaneous regression of untreated tumors suggests that immune recognition plays a role in tumor resolution. Anecdotal reports of successful vaccination therapy exist, but controlled studies are rare. In one report, successful resolution was achieved in 11 of 12 horses treated with an autogenous tumor vaccine. A second vaccination protocol resulted in resolution of the one recurrence. All 12 cases had no previous tumor treatment. A lower success rate was reported in horses with previously treated, recurrent sarco ids.

With large, aggressive, or multiple tumors, it is recommended that a combination of treatment modalities be employed. At the Veterinary Teaching Hospital at Michigan State University, surgical excision or laser ablation is commonly combined with intralesional chemotherapy or radiation therapy. Unfortunately, these combination treatment regimens are expensive and require a significant time commitment from the owner or caretaker of the patient.

SQUAMOUS CELL CARCINOMA

Epidemiology

Squamous cell carcinoma (SCC), a malignant, locally invasive neoplasia of squamous epithelial cells, is the second most common tumor in horses. Although SCC can develop anywhere on the integument, sites of predilection include areas lacking pigmentation, poorly haired regions, and skin near mucocutaneous junctions. SCC is the most common neoplasm of the equine eye, conjunctiva, ocular adnexal structures, and external genitalia. It has also been reported in the nasal cavity, paranasal sinuses, pharynx, larynx, and hoof capsule, and it should be considered in horses with chronic, refractory foot abscesses. Ultraviolet light-induced damage is thought to predispose to SCC. Many tumors arise from precancerous lesions, including actinic keratitis, carcinoma in situ, squamous metaplasia of the penile epithelium, and irritant-induced chronic keratitis. Proposed irritants include topically applied chemicals, smegma, and flies. SCC has been reported to develop in areas of chronic, poorly healing wounds and at sites of previous burn injury. Breeds with poorly pigmented, pink-skinned areas including Appaloosas and paint-colored horses are more prone to develop SCC; 69% of all ocular SCC cases occur in individuals lacking periocular pigmentation. It has been suggested that draft breeds have an increased incidence of SCC.

Tumors are classified as ulcerative or proliferative and generally arise as solitary lesions. Ulcerative SCC may develop over time, with early lesions appearing as small nodules underlying normal-hair ed skin. Ulcerative lesions can be mistaken for nonhealing wounds and chronic granulation tissue, resulting in delayed treatment. Ocular lesions can begin as small ulcerative lesions on lid margins, or as keratotic plaques on the cornea, so SCC should be suspected whenever raised red lesions appear on the lid margins, sclera, or conjunctiva, particularly in unpigmented skin (Fig. 29-2). Squamous cell carcinoma of the ocular structures can invade the orbit, calvarium, tear duct, and sinuses if left untreated. Proliferative pedunculated lesions on the penis often have a cauliflower-like appearance. SCC typically spreads to surrounding tissues and local lymph nodes, but distant metastasis is rare (see Chapter 66). Tumors with local or distant metastases or large, invasive tumors have a poor prognosis for cure.

Treatment

Surgical excision, radiation therapy, topical application of antimitotics, intralesional chemotherapy, cryotherapy, laser excision, hyperthermia, and immunotherapy have all been successfully used to treat equine SCC. Surgical excision alone should be reserved for small tumors and has a better overall success rate when combined with adjunctive therapies such as chemotherapy, cryotherapy, or radiation therapy. Keratoplasty with or without adjunctive radiation therapy has been used successfully to treat corneal SCC. Cryotherapy is reported to be most useful in small periorcular lesions and lesions arising from the external genitalia. Larger lesions may benefit from surgical debulking prior to cryotherapy. Frequent reexamination is recommended to monitor regrowth and may be the most important determinant of success. Failure to retreat small recurrences quickly may allow tumor regrowth and failure of the treatment protocol.

Irradiation

Several radiation modalities have been used to successfully treat SCC, including external beam radiotherapy, implanted...
radiation devices, and β-emitting wands. Strontium wands (β-radiation) can be used to treat small superficial plaques on the cornea, sclera, or conjunctiva.68-70 Beta irradiation has a very short penetration depth, making it extremely useful for small corneal lesions; an 89% nonrecurrence rate was reported in one study.69 Both radioactive implants and external beam therapy have been reported as successful in the treatment of SCC.40,71-73 External beam therapy can be performed on an outpatient basis, whereas radiation implants require hospitalization and special housing during treatment protocols. Radiation therapy is generally limited to referral practices because of the licensure requirement, specialized equipment, and housing requirements.

**Intralesional Chemotherapy**

Intralesional chemotherapy is very effective in treating SCC, whether as an adjunctive treatment after surgical cytoreduction or as a sole treatment protocol.44,45 *Cisplatin* binds directly to DNA and inhibits its synthesis in dividing cells. Mixing cisplatin in an oily emulsion creates a reservoir effect, maintaining the drug in the local tissues for a prolonged period of time. Intralesional cisplatin in oily emulsion used with or without surgical cytoreduction has a 2-year local control rate of 89% for SCC. Overall success is better with SCC of the external genitalia than with periocular SCC. Cosmetic results are generally excellent. Drawbacks include the multiple treatments needed, the expense, and potential exposure of the staff, but overall success rates are high.

**Topical Chemotherapy**

Topical 5-fluorouracil, with or without surgical débridement, has a reported success rate of 90% in the treatment of SCC of the male external genitalia.74 In another small case series, three individuals with superficial SCC were successfully treated with repeated application of topical 5-FU.75 Topical application was associated with local inflammation and swelling. The use of 5-FU as a sole treatment modality is best reserved for small superficial tumors.

Successful treatment of a recurrent SCC of the lower lip using the nonsteroidal anti-inflammatory *piroxicam* is reported.76 Nonsteroidal anti-inflammatory drugs inhibit cyclooxygenase (COX) enzymes that catalyze the conversion of arachidonic acid to prostaglandins. Overexpression of the COX-2 enzyme by neoplastic tissue has been reported.77 Both the lower lip and metastatic lesions resolved with oral *piroxicam* therapy. No recurrence was reported in the 5-year follow-up. Successful treatment of periocular SCC using immunotherapy has also been reported, but case numbers are small.78

In a retrospective study of 43 horses with ocular SCC, nonrecurrence rates were 55.6% for surgical excision, 75% for radiation therapy, and 33.4% for cryotherapy, and combination therapy had a greater success rate than single-modality treatment.82 In a retrospective study of 147 cases of ocular/adnexal SCC, factors that influenced survival included tumor location and size. Prior treatment modalities, the presence of multiple tumors, and treatment modality used at the time of examination did not influence survival.79

**MELANOMA**

**Epidemiology**

Equine melanoma is one of the most common skin tumors in horses. Histopathologic surveys report that melanomas comprise 4% to 15% of all skin tumors.58,80 The vast majority of melanomas occur in gray horses; breed predispositions are most likely caused by the incidence of the color gray within a breed. Virtually all gray horses will develop melanoma over time. In a population study of Lipizzan horses, less than 6% of horses 16 years of age or older were melanoma free.81 Melanocytic tumors in gray horses are thought to arise because of a disturbance in melanin transfer from dermal melanocytes to follicular cells.82 Progression from melanocyte accumulation to melanoma formation has been documented in melanoma-prone locations. Interestingly, sites of predilection are the first areas to show depigmentation changes (vitiligo) with aging.83 There are four types of equine melanomas: melanocytic nevi, dermal melanomas, dermal melanomatosis, and malignant melanomas.84 *Melanocytic nevi* are composed of larger pleomorphic melanocytes with an increased number of mitotic figures, binucleate cells, and variable cytoplasmic pigmentation. Melanocytic nevi are typically single or multiple discrete nodules and are found in similar frequency in both gray and nongray individuals.84

*Dermal melanoma* and *melanomatosis* appear benign on histopathologic examination and are composed of smaller, homogenous dendritic cells with condensed chromatin, dense
pigmentation, and no visible mitosis. Dermal melanomas originate in the deeper dermis and are typically small singular or multiple nodules (Fig. 29-3). Dermal melanomatosis is defined as confluent multiple large melanomas. The risk of dermal melanomatosis increases with age and its occurrence is associated with an increased risk of metastases. True malignant melanomas are rare and are classified on the basis of the presence of both histopathologic and clinical characteristics of malignancy. In one retrospective study, only two of 53 cases were classified as malignant. Both occurred in aged horses (older than 20 years), and both recurred within 10 months after surgical excision. Malignant melanomas are frequently invasive and associated with a poor prognosis for complete resolution.

The vast majority of melanomas are located around the perineum and base of the tail, with lesions around the head (lips, eyes, parotid region) and other sites less frequently reported. Melanomas have also been reported in the foot, meninges, thorax, ocular structures, and abdominal cavity. These unusual locations appear to be associated with a poor prognosis.

**Treatment**

Despite their histopathologic differences, dermal melanomas and melanocytic nevi have similar clinical characteristics, and surgical excision is curative in the majority of cases. Smaller lesions can be sharply excised; alternatively, the use of the CO2 laser has been recommended. The ability to cauterize the wound bed and control hemorrhage makes laser excision particularly useful in sites where primary closure cannot be achieved (e.g., the base of the tail).

Complete excision is difficult with larger lesions such as dermal melanomatosis, but surgical debulking can be palliative. Oral cimetidine has been recommended to treat melanomas, particularly larger lesions and those exhibiting a rapid growth phase. Cimetidine has antitumor activity and is a histamine receptor antagonist. Immunomodulation of lymphocyte activity via histamine receptor interaction is postulated to be a mechanism of antitumor activity. Reports of the effectiveness of cimetidine in the treatment of equine melanoma are variable. Response is reported to be the highest in tumors exhibiting a rapid growth phase; successful response was achieved using a dose of 2.5 mg/kg every 8 hours. The frequency of dosing may be the most critical factor in predicting clinical response. Treatment is recommended for 3 months, or for 3 weeks after cessation of tumor growth. Although a complete cure has rarely been reported, cimetidine may have some benefit in halting rapidly growing tumors and returning them to a more quiescent state.

Additional treatments for equine melanoma include intralesional chemotherapy and cryotherapy. Successful treatment of smaller nodules has been reported using intralesional cisplatin, and this is beneficial in decreasing the size of larger tumors prior to surgical excision.

A melanoma vaccine is available and has been reported to have some success. The successful treatment of equine melanoma using intratumoral injections of human interleukin (IL)-12 has also been reported.

In one study that examined melanomas in a population of gray horses, all patients exhibited normal quality of life regardless of tumor number and type. Consequently, it is frequently suggested that melanomas be treated with benign neglect, as they are rarely the cause of significant disease in affected horses. However, with age, the risk of progression to dermal melanomatosis and metastases increases. Small nodules are easily removed and rarely recur, but owners need to be informed that new tumors will quite likely develop over time. Although conservative management is reasonable in the majority of cases, more aggressive treatment, including early removal of smaller tumors, may decrease the risk of melanomatosis or metastases as the animal ages.

Malignant melanomas have a higher recurrence rate with simple excision. Combination therapy, including surgical debulking and intralesional chemotherapeutic injections, may offer palliation, but the prognosis for cure is poor.

**MASTIT TUMORS**

**Epidemiology**

Equine cutaneous mastocytosis (ECM) is less common in horses than in small animals. The benign, solitary, nodular cutaneous form is the most common, although malignant ECM and congenital disseminated forms have been recognized. It has been suggested that the benign nodular form is not a true neoplasia and is instead the result of an inflammatory reaction to dysplastic mast cells and recruited eosinophils. The release of inflammatory products from accumulated eosinophils and mast cells results in necrosis, and later a granulomatous reaction develops with fibrosis and subsequent encapsulation of the nodule. The histopathologic findings of a necrotic focus, a granulomatous inflammatory response, and fibrosis surrounding well-differentiated mast cells differentiates equine cutaneous nodular mastocytosis from malignant ECM, which contains abnormal mast cells with increased nuclear-to-cytoplasmic ratios, anisokaryosis, and increased mitotic figures.

**Treatment**

The majority of cutaneous nodular ECMs are successfully treated with wide surgical excision (margins of 1 cm or greater). Reports of resolution after incomplete resection...
exist. Intraleisional injection of glucocorticoids has also been used to successfully treat cutaneous nodular ECM. Malignant ECM is not responsive to surgical excision and is associated with a poor prognosis for cure.

LIPOMAS

Epidemiology

External lipomas are a relatively uncommon neoplasia in horses. Unlike mesenteric lipomas, they are principally found in young horses. Subcutaneous lipomas are generally encapsulated, singular, nonpainful masses that are fluctuant to firm on palpation, although infiltrative lipomas have been reported in the horse. Sites of occurrence include the limbs, thorax, abdominal wall, and eyelids. Histopathologic examination reveals encapsulated well-differentiated adipocytes. Infiltrative lipomas consist of similar cell types infiltrating surrounding muscle tissue.

Treatment

Lipomas are generally encapsulated, slow-growing masses, and thus they are benign, clinically insignificant, and typically a cosmetic concern only. Surgical excision is reported to be curative in all cases; recurrence has not been reported even with incomplete excision of infiltrative or large lipomas.

CUTANEOUS HABRONEMIASIS

Epidemiology

Cutaneous habronemiasis is a proliferative ulcerative lesion produced by aberrant migration of the larvae of three endoparasites (Habronema muscae, Habronema microstoma, and Draschia megastoma) that inhabit the stomach of horses. Eggs, shed in the feces of horses, hatch, and the larvae are ingested by maggots of the house fly, Musca domestica, or the stable fly, Stomoxys calcitrans. Third-stage infective larvae migrate to the head of the fly and are passed to the horse when the fly feeds on a warm, wet surface. The larvae are then swallowed by the horse and mature in the stomach. The cutaneous form, also called summer sores, develops when larvae attached to wound beds or abraded moist surfaces, including the penis, prepuce, and ocular adnexa. Lesions are most commonly seen on the penis, in cutaneous wounds, or around the eye. The proliferative, ulcerative, granulomatous lesions are thought to result from a hypersensitivity reaction to the larvae, and mild to severe pruritus may develop.

Ophthalmic habronemiasis can develop in the conjunctiva or nasolacrimal ducts, resulting in third-eyelid granulomas or granulating ulcers below the medial canthus. Clinical signs include epiphora, chemosis, and photophobia. The presence of pale yellow granular material, or the finding of larvae on impression smears, may aid in the diagnosis. Histopathologic examination is recommended, because habronemiasis can develop secondary to an underlying neoplastic or infectious condition. The incidence of disease has declined dramatically since the development of ivermectin anthelmintics. Lesions occur principally in warm months and are associated with increased fly populations and poor manure collection.

Treatment

Lesions have been reported to resolve with onset of cooler weather. Treatment is aimed at reducing the size of the lesions, resolving the inflammatory or allergic component, and preventing reinfestation. Treatment with systemic ivermectin will kill migrating larvae but may not result in resolution of the lesion, because the dead parasite can continue to cause a severe inflammatory reaction. In some cases, oral ivermectin results in an increase in pruritus and self-trauma. Larger masses may require surgical cytoreduction. The intraleisional injection of corticosteroid is recommended to decrease the allergic or inflammatory reaction to the larvae. Successful resolution using systemic corticosteroids alone has been reported. Re-infestation can be prevented by application of topical organophosphates or by placing the wound under a bandage. Topical preparations that combine organophosphates, corticosteroids, dimethyl sulfoxide, and nitrofurazone have been used. The ophthalmic form of habronemiasis can be treated with oral ivermectin, topical corticosteroid eye drops, and curettage. Careful assessment of the corneal integrity should be made prior to the use of ophthalmic corticosteroids.

PYTHIOSIS

Epidemiology

Pythiosis is a cutaneous disease caused by invasion of the organism Pythium insidiosum, a fungus-like oomycete. The disease occurs principally in warm, tropical regions; the organism has an aquatic life cycle and requires relatively warm temperatures for reproduction. Pythiosis is commonly seen in the southern United States during the late summer and early fall. Horses are infected when invasion occurs through small wounds or skin breaks, typically in lakes, swamps, or flooded lands. Zoospores, released during reproduction, are attracted to organic debris and invade open wounds. Characteristic lesions are ulcerative masses of granulation tissue. Rapid enlargement can occur, even within a matter of days. Pythiosis is often pruritic; sinus tracts are visible and often contain gritty, coral-like masses, called "kunker" or "leeches." Kunker are made of necrotic tissue and are thought to result from a hypersensitivity reaction to the larvae, and mild to severe pruritus may develop.

Ophthalmic pythiosis can develop in the conjunctiva or nasolacrimal ducts, resulting in third-eyelid granulomas or granulating ulcers below the medial canthus. Clinical signs include epiphora, chemosis, and photophobia. The presence of pale yellow granular material, or the finding of larvae on impression smears, may aid in the diagnosis. Histopathologic examination is recommended, because pythiosis can develop secondary to an underlying neoplastic or infectious condition. The incidence of disease has declined dramatically since the development of ivermectin anthelmintics. Lesions occur principally in warm months and are associated with increased fly populations and poor manure collection.

Treatment

Lesions have been reported to resolve with onset of cooler weather. Treatment is aimed at reducing the size of the lesions, resolving the inflammatory or allergic component, and preventing reinfestation. Treatment with systemic ivermectin will kill migrating larvae but may not result in resolution of the lesion, because the dead parasite can continue to cause a severe inflammatory reaction. In some cases, oral ivermectin results in an increase in pruritus and self-trauma. Larger masses may require surgical cytoreduction. The intraleisional injection of corticosteroid is recommended to decrease the allergic or inflammatory reaction to the larvae. Successful resolution using systemic corticosteroids alone has been reported. Re-infestation can be prevented by application of topical organophosphates or by placing the wound under a bandage. Topical preparations that combine organophosphates, corticosteroids, dimethyl sulfoxide, and nitrofurazone have been used. The ophthalmic form of habronemiasis can be treated with oral ivermectin, topical corticosteroid eye drops, and curettage. Careful assessment of the corneal integrity should be made prior to the use of ophthalmic corticosteroids.
the horse is cured. Sodium iodide administered intravenously has been recommended as an adjunctive therapy.126

In addition, a topical dressing containing 50 mg amphotericin B, 10 mL sterile water, and 10 mL dimethyl sulfoxide is recommended.127 Because amphotericin B is nephrotoxic, serum creatinine, urea nitrogen, hydration status, water consumption, and urine output should be closely monitored. Reported side effects of amphotericin B include depression, anorexia, pyrexia, and urticaria.

Immunotherapy using a vaccine made from fungal cultures is reportedly curative if administered early in the course of the disease.128 In a study of 40 horses with pythiosis, 53% were cured with vaccination alone. Surgical cytoreduction combined with vaccination improved success rates if vaccination was performed within 2 weeks of surgical débridement.129

NODULAR NECROBIOsis

Epidemiology

Nodular necrobiosis, also called collagenolytic granulomas or eosinophilic granulomas with collagen degeneration, is reported to be one of the most common skin diseases in horses.124 The underlying etiology is unclear; insect hypersensitivity has been proposed, and the propensity for lesions to develop at pressure points (under the saddle region, in particular) suggests trauma may play a role.125 Diagnosis is based on histopathologic findings of a granulomatous reaction containing eosinophils, lymphocytes, and histiocytes, with collagen degeneration.126 Typical lesions are 0.5- to 1.0-cm subcutaneous nodules and are most commonly found on the withers and dorsum but can occur anywhere on the body. The differential diagnosis includes equine amyloidosis, foreign body granuloma, dermoid cysts, habronemiasis, equine sarcoid, and other neoplasia.

Treatment

Single asymptomatic lesions that are not a cosmetic concern can be left untreated. Single lesions can be surgically excised. Alternatively, intralesional injection of glucocorticoids such as triamcinolone acetonide (3 to 5 mg per lesion) or methylprednisolone acetate (5 to 10 mg per lesion) can be performed.127 Lesions that are calcified can be difficult to inject and may require surgical excision.102 Systemic corticosteroids have been recommended to treat multiple lesions—for example, prednisolone at 1 mg/kg orally, daily for 14 days, followed by 0.5 mg/kg orally for an additional 14 days. Lesions may recur and require multiple retreatments for resolution.

PAPILLOMATOSIS

Epidemiology

Papillomaviruses are very host and tissue specific and are the causative agents of the majority of warts seen in mammals. Equine papillomatosis and aural plaques are caused by equine papillomaviruses (EqPV).127 Papillomaviruses infect the basal layer of the epithelium, resulting in an abnormal proliferation and hyperkeratosis of the epithelium. Clinical syndromes include aural plaques and juvenile papillomas (juvenile warts). Congenital neonatal papillomatosis was thought to be the result of in utero infection by papillomavirus; however, recent reports suggest that congenital papillomatosis is in reality a hamartomatous lesion and not a virus-induced growth.128 Affected foals are born with a large wartlike lesion located anywhere on the integument.

Juvenile Papillomatosis

Juvenile papillomatosis most commonly occurs in young horses (6 months to 4 years), but older horses can be affected. Multiple small (5-mm) gray-pink, vegetative, cauliflower-like warts usually develop on the lips, muzzle, face, distal limbs, and external genitalia. Lesions can be spread by direct contact, contamination of the local environment, and vectors. Large numbers of infectious virus are shed in the superficial keratinocytes.

Aural Plaques

Aural plaques are raised, white or tan, smooth plaques arising on the internal surface of the pinnae (Fig. 29-4). Fly irritation may exacerbate these lesions, making them crack and causing the horse discomfort. Equine papillomavirus DNA has been identified in both aural plaques and juvenile papillomas, but different viral subtypes are suspected.

Treatment

Congenital papillomas can be removed surgically or ligated and allowed to undergo necrosis. In the majority of cases, juvenile warts will spontaneously regress once immune recognition occurs. Immunologic compromise may result in failure to regress; in these cases, surgical excision may be necessary. Vaccination using wart tissue has been recommended.129 Alternative treatments include cryotherapy, intralesional chemotherapy, and radiofrequency hyperthermia.

Historically, treatment protocols for aural plaques have been unrewarding, although successful resolution using laser ablation has recently been reported. The lesions are manually débrided with a dry gauze pad to remove...
keratinous debris, and then the lesions are lightly painted with the laser probe. Recurrence has not been reported.\textsuperscript{130}

**DENTIGEROUS CYSTS**

**Etiology**

A dentigerous cyst is a congenital defect. It arises as a result of incomplete closure of the first branchial cleft during embryologic development. By definition, dentigerous cysts contain dental elements, such as enamel, dentin, and cementum.\textsuperscript{13 1} The epidermal lining differentiates as does normal epidermis, and the cyst becomes nodular as it begins to fill with keratin. Lesions are usually asymptomatic. They may be present from birth, but they remain unnoticed until they enlarge.\textsuperscript{130,132} They typically appear as a unilateral swelling at the base of the ear but can occur in other locations on the head and sinuses.\textsuperscript{13 1-134} The secretory, cystic lining produces a mucoid fluid that may drain intermittently from the nodule. Diagnosis is frequently made on the basis of location, clinical history, and the presence of pale yellow, mucoid, cystic fluid.\textsuperscript{132} Definitive diagnosis requires surgical excision and histopathologic examination.

**Treatment**

No treatment is required. However, if desired, surgical excision with complete extirpation of the cyst lining is necessary to prevent recurrence.\textsuperscript{133} Preoperative radiographic evaluation is recommended to determine the location of dental material and the number of cysts, and prior to anesthesia, the extent of the cyst should be defined by careful palpation. The preparation and surgical scrub should include the pinnae to allow manipulation during surgery. The sinus tract, which is identified using a malleable probe (Fig. 29-5), is opened and the neck of the cyst sealed with a ligature prior to dissection. The plane of dissection should be as close to the wall of the cyst as possible to prevent damage to the auriculopalpebral nerve and auricular muscles, as well as to minimize hemorrhage. Distention of the cyst aids in its identification and removal. The auricular muscles are small and can be difficult to visualize because of the aberrant connective tissue associated with the dentigerous cyst. Opening the cyst should be avoided at all cost; spillage can result in contamination of the incision site and result in infection, dehiscence, and excessive scarring. The dental tissue can vary in size from a small and easily removable tooth to large areas of enamel-covered bone. Careful excision using a chisel or drill is required in such cases to prevent damage to the cranial and brain.\textsuperscript{133} Failure to remove all the dental tissue may result in dehiscence and refistulization. Auricular muscles and fascial layers are apposed with 3-0 polydioxanone, and skin closure is routine. Postoperative antibiotics are not routinely indicated, although anti-inflammatory drugs are recommended, particularly when forceful extraction of dental tissue was required. In one report, an ectopic tooth was found compressing the cerebellum.\textsuperscript{133}

DENTISTRY

After almost a century of inactivity, equine dentistry has made rapid progress over the past 10 years, and equine dental disorders are now documented as one of the most common diseases recognized by U.S. practitioners. Additionally, up to 10% of British equine practitioners’ time is spent dealing with dental-related disorders. This part of the chapter will concentrate on the many surgical aspects of this expanding field of study. The modified Triadan system of dental nomenclature (Fig. 30-1) is used here.

Examination of the Oral Cavity and Teeth

The equine incisors and canine teeth are readily examined in the unsedated horse. With the mouth closed, the rostral aspect of the mandible should be pushed sideways and the distance of lateral movement of the lower incisors in relation to their upper counterparts (e.g., 1 cm) prior to separation of the incisors (as the angled occlusal surfaces of opposing cheek teeth [CT] come into contact) should be measured. This measurement can be used to assess the angulation of the CT occlusal surfaces and can also detect the presence of major CT overgrowths. This maneuver is easier to perform in sedated horses, as is visual examination of the oral cavity. Because of a combination of factors, including the limited angle of opening of the equine mouth (common to all herbivores), the rostral positioning of the lip commissures, and the length of the equine CT rows, it is very difficult to visually examine the CT, particularly in unsedated horses. Palpation through the cheeks may reveal food pocketing or major dental irregularities (such as a displaced or missing maxillary CT, or a large overgrowth of the rostral CT). Even if no abnormalities are palpable, stimulation of a pain response during this palpation may indicate the presence of sharp overgrowths on the lateral aspect of the upper CT. A useful test for suspected cases of dental disease is to feed the (unsedated) horse a small amount of forage. Affected horses may not make the normal vigorous crunching sounds of mastication, may show restricted mandibular movements that may be confined to one side of the mouth, or may quid (drop boluses of partially masticated forage) if a painful dental disease is present.

A detailed equine oral examination can only be performed using a full mouth speculum (gag), and every equine practitioner should have one (Fig. 30-2). It is possible to perform a safe digital examination of the CT and oral cavity of most unsedated horses, but a more complete visual examination requires sedation, especially with

**Figure 30-1.** The modified Triadan system of equine dental nomenclature. To identify deciduous teeth, add 4 to the first number of its permanent successor. For example, the deciduous incisor 501 is replaced by permanent incisor 101.

**Figure 30-2.** This horse is having a dental examination while being restrained in stocks, which has an overhead extension to allow a dental head collar to be attached. Note the use of the Hausmann speculum and headlight for this examination.
painful disorders and in difficult horses. Food retained in the oral cavity should be removed by flushing the mouth using a large dental (dosing) syringe and water or a very dilute chlorhexidine solution. The use of a strong headlight (a hand-held light is much less satisfactory), a dental probe or metal examination “basket” to displace the tongue, and an equine dental mirror (or a rigid dental endoscope, if available) allows full visual examination of the equine oral cavity.

Unless each tooth and the adjacent soft tissues (gums, cheeks, and tongue) are carefully visualized and palpated, major disorders, especially of the caudal CT and of the adjacent periodontal membranes, can readily be missed. A long dental mirror or intraoral endoscope is essential to examine the gingival margins of the CT, especially their buccal aspects, and also to visualize their occlusal surfaces (e.g., to detect pulpar exposure and more fully assess dental fractures and infundibular caries). It is also useful to smell the oral cavity for halitosis, which usually indicates anaerobic infections—most commonly as a result of periodontal food pocketing with infection, but occasionally caused by advanced dental infections (caries) or CT fractures.

A very significant disorder, especially in the younger horse, is CT apical (the roots are often not yet even formed) abscessation. In most cases, little obvious change is visible on the clinical crown, except with some maxillary CT apical infections, where gross infundibular caries or sagittal fractures of the clinical crown may be present. However, close examination of the occlusal surface of the suspect CT with a dental mirror or endoscope, and probing the secondary dentine on the occlusal surface with a fine steel probe, will reveal pulpar exposure (i.e., dull, darker areas of the secondary dentine, with pitting and food pocketing into the pulp chamber) in about 25% of infected teeth. This finding can be of enormous value when other clinical findings and radiology are inconclusive in cases of apical infection.

Disorders of the Incisors

Overjet and Overbite (“Parrot Mouth”)

Many horses have some degree of what the older textbooks term mandibular brachygnaithism (“parrot mouth,” “overshot jaw”)—that is, a rostral projection of the upper incisors beyond the lower incisors in a horizontal direction, which should be termed “overbite.” However, in some of these cases, there may not be shortness of the mandible. Instead, an overlong maxilla (maxillary prognathism) may be present. Both of these conditions induce CT wear disorders. Consequently, a major significance of overjet is that it very commonly occurs with overgrowths of the rostral aspects of 106 and 206 and of the caudal aspects of 311 and 411. In older horses with overjet, the reduced wear on upper incisors 101 and 201, in particular, may cause them to overgrow, and the upper incisors subsequently develop a convex occlusal surface, which has been termed a “smile.” In more severe cases, the upper incisors lie rostral to the lower incisors in a vertical direction (i.e., overbite), and this may prevent the small, normal amount of rostrocaudal mandibular movement that occurs in horses, and it may even retard mandibular growth, thus exacerbating CT abnormalities. Unless contact between opposing incisors is totally absent, overjet/overbite rarely causes the horse trouble in prehend-
oral cavity along the lateral aspect of the CT. As the last of the wire is pulled through the cheek incision, a kink will occur in it, and this area of weak wire should later be discarded.

The two free ends of the wire are withdrawn from the mouth, on either side of the cheek teeth, while making them even in length. While pulling them rostrally, the free ends are twisted back to the rostral border of the upper 06s, as dorsally as possible. The twisted wires are then placed over the labial (rostral) aspect of the incisors. This procedure is then repeated on the other side of the mouth, and the free ends of the both pairs of wires are twisted tightly together, just below the gingival borders of the upper incisors (or interwoven between some incisors at the gingival level) and their ends are trimmed (Fig. 30-5). The wire knot can be embedded in acrylic to prevent soft tissue trauma.

If overbite is also present in such foals, the tension from this orthodontic brace may well cause further caudoventral deviation of the upper incisors and premaxilla toward the rostral aspect of the lower incisors, and this would simply worsen the overbite, rather than retard premaxillary and maxillary bone growth. In such foals, a "biteplate" can additionally be fitted along with the orthodontic brace to promote indirect occlusion between the upper and lower incisors. The biteplate can be fashioned from a perforated aluminium plate (2 to 4 mm thick) that is cut to fit the shape of the rostral aspect of the hard palate, extending caudally about 4 to 5 cm from the incisors. The biteplate should be raised caudally, so that the sloped plate will tend to push the lower incisors more rostrally during prehension.

Having fitted the brace as just described, the underlying hard palate is covered in Vaseline, and the bite plate, covered in wet acrylic, is placed on the hard palate. Additional acrylic is used to join the biteplate to the wires of the brace (Fig. 30-6), ensuring that the acrylic does not extend too high on the gingiva above the incisors, where it can form a sharp rim that can traumatize the lip mucosa. After a biteplate is fitted, foals may have trouble suckling. The biteplate may also hurt the mare's udder during suckling, causing her to temporarily prevent the foal from suckling. In such cases, the mare should be milked for a few days and the foal bottle fed with her milk. If the foal is uncomfortable because of the brace, it should be given low doses of nonsteroidal anti-inflammatory drugs and anti-gastric ulcer medication, such as omeprazole. Some clinicians recommend that foals be weaned before fitting orthodontic braces with biteplates. Any overgrowths on the rostral aspects of the upper 06s and on the caudal aspects of the lower 08s should be rasped off, to promote free rostrocaudal mandibular movement.

Wires may break unilaterally or bilaterally and thus cause the biteplate to loosen. Consequently, the foal's mouth needs to be regularly inspected, and broken wires need to be replaced, usually under general anesthesia. The brace can be removed when the incisors are aligned or nearly so. With severe overjet or overbite, complete resolution may not be possible, but aesthetically pleasing results, and certainly much reduction in the concurrent CT overgrowths, can be achieved. The ethics of these orthodontic procedures,
especially in animals that may be used for breeding, are
debatable, and some breed societies do not allow registra-
tion of horses that have been treated with this technique.
This aspect has to be discussed with the owners in detail
before orthodontic wires and biteplates are applied.

Orthodontic treatment is not feasible in adult horses.
Large overjet/overbite incisor overgrowths in adult horses
should be reduced if very overgrown, using power or manual
instruments, in stages of about 5 mm, to prevent pulpar
exposure. To remove incisor overgrowths, it is best to sedate
the horse and use a plastic pipe in the interdental space
(circular metal gags, such as Swale’s gag, can fracture CT,
and rubber wedge gags promote constant chewing). Once
the overgrown incisors have been reasonably reduced, they
should be rasped level biannually, as should concurrent CT
overgrowths (see “Disorders of the Cheek Teeth,” p. 327).

Underbite (“Sow Mouth”)
Prognathism (“undershot jaw,” “underbite”) is uncommon
in the horse, except in miniature horses, and is also usually
clinically insignificant unless there is a total lack of occlu-
sion between the upper and lower incisors. Severely affected
horses eventually develop a concave upper incisor occlusal
surface, which has been termed a “frown” and may develop
lower 06 and upper 11 overgrowths.

Correction may be achieved using the same orthodontic
procedures as discussed just previously.

Retained Deciduous Incisors
Deciduous incisors, which normally lie rostral (i.e., labial)
to their permanent counterparts, are occasionally retained
beyond their normal time of shedding, and they will then
cause the permanent incisor to be displaced caudally, and
they may even cause permanent changes in the incisor
occlusal surface. If retained incisors are very loose, they can
be removed using small-animal dental extraction forceps or
equine “wolf teeth” forceps. If more firmly attached, they
should be extracted under sedation and local anesthesia (by
injecting 2 to 5 mL lidocaine, directed 2 to 4 cm caudally,
into the ostium of the mental or infraorbital canal) using a
small-animal dental elevator. If a permanent incisor does
not erupt beneath its deciduous predecessor, little
resorption of its reserve crown may occur and up to 6 cm of
the deciduous reserve crown may remain in the alveolus.
In such cases, some of the rostral aspect of the alveolus will
have to be removed with a bone chisel to extract the retained
incisor (Fig. 30-7). Occasionally, a permanent incisor will
erupt rostrally to the deciduous incisor and great care must
be taken in removing the deciduous incisor that is now
positioned on the caudal (lingual) aspect of the permanent
incisor.9

Supernumerary Incisors
Supernumerary incisors are permanent teeth that are
additional to the normal six permanent incisors on each
arcade and must be differentiated from retained incisors.
Supernumerary incisors may have long (greater than 7.0 cm)
reserve crowns that may be intimately related to the reserve
crowns and roots of the normal permanent incisors, and
therefore they are usually impossible to differentiate, both
clinically and radiographically, from normal incisors.10
Consequently, extraction of supernumerary incisors is tech-
ically very difficult and also risks damaging the normal
teeth. If they are grossly displaced rostrally (labially) and
thus protrude submucosally, they are amenable to extrac-
tion, as described for a large retained deciduous incisor. As
most supernumerary incisors cause few clinical problems,
they are usually best left alone (except, perhaps, in show
horses), with biannual rasping of any incisors that are not in
occlusion to prevent overgrowths.

Fractures of the Incisors
Fractures of the incisor teeth, and often of their supporting
mandibular or premaxillary bones, can occur because of
trauma (usually from kicks) and commonly result in
exposure of the pulp (i.e., complicated dental fractures).10,11
Idiopathic incisor fractures are rare, in contrast to fractures
of the CT. All young equine teeth (incisors and CT) have very
wide apical foramina (root canal openings), along with a
very large, vascular pulp, which can resist the infection, and
more so the inflammation, that inevitably develops in orally
exposed pulp.12 Consequently, pulpar exposure, especially
in younger horses, does not necessarily lead to the degree of
pulpar inflammation that compresses its vascular supply
(with subsequent pulpar ischemia and necrosis, and death
of the tooth), as usually occurs with pulpar exposure in
brachydont (e.g., human or canine) teeth. Cases of incisor
fracture should receive tetanus prophylaxis and prolonged
(7 to 10 days) antibiotic (e.g., trimethoprim/sulfadiazine)
therapy.

Endodontic (root canal) treatment can be performed
through the damaged occlusal aspect to help save the tooth.
This usually consists of vital pulpotomy—that is, removal
of devitalized pulp with a fine-pointed scalpel, control of
hemorrhage from the underlying vital pulp with paper
“points” or hemostatic agents, followed by sealing the healthy
pulp with a calcium hydroxide preparation that promotes

Figure 30-7. This horse has a large retained 702 (deciduous precursor
of 302), and minimal resorption of its apex and reserve crown has
occurred. A lingual (caudal) deviation of the permanent tooth is now
present that would cause a permanent incisor malocclusion. About 5 cm
of the rostral aspect of the alveolar wall of 702 was removed (white
arrows). The tooth was then loosened with elevators and is now being
extracted with incisor forceps.
reparative tertiary dentine formation at this site. Having sealed off the vital pulp, the remaining open pulp canal should now be prepared for filling by etching it for 1 minute with a phosphoric acid gel (to make the dental surface more porous to bond to dental restorative materials), which is then flushed away with water and air-dried. The pulp canal is then thinly coated with a bonding agent (Fig. 30-8) and sealed with a modern, compound restorative material (Fig. 30-9).

Alternatively, débridement of the exposed pulp and application of calcium hydroxide paste, along with the antibiotic treatment described, could be performed by veterinarians who are not dental specialists. In some young horses, the pulp becomes sealed off at the site of exposure by reparative (tertiary) dentine formation even without treatment, with the tooth remaining vital and continuing to erupt normally.10 Treatment of premaxillary and mandibular fractures involving the incisors is discussed in Chapter 103.

Abnormalities of Incisor Wear

Incisor disorders include rectangular overgrowth of individual incisors (“steps”) as a result of traumatic loss, or of maleruption (e.g., delayed eruption or displacement) of the opposing teeth, in addition to the previously noted incisor overgrowths occurring with overjet or underjet. Abnormal wear pattern of the rostral aspect of the 01s and occasionally of the 02s occurs in crib biters. Another common abnormality of incisor wear is a tilted or slanted incisor occlusal surface—that is termed “slope mouth” or “slant mouth.” This defect is invariably associated with a major unilateral abnormality of the CT that has caused a pronounced unilateral chewing action, which causes uneven wear of the incisors.10,15 The disorder of “wry nose” can also cause this incisor defect as a result of incisor malocclusion. Such incisor overgrowths should be reduced as previously described. The practice of arbitrarily reducing the height of the incisor, sometimes very extensively, purportedly to allow the CT to develop better occlusal contact (“incisor bite alignment techniques”) has little scientific or clinical merit and should be avoided.

Disorders of the Canine Teeth (Triadan 04s)

Occasionally, displaced or grossly enlarged canine teeth interfere with the bit. Such teeth should be ground down, retaining at least 1 cm of crown above the gingiva, to avoid pulpar exposure that may cause pulpitis and possibly death of the tooth, which may not become evident until years later.14 The sharp tips, or even most of the clinical crown of the canine teeth, are rasped off by some operators to prevent these teeth from causing lacerations of the operator’s hands during dental procedures and allegedly to prevent them from interfering with the bits.

Rarely, canines may need to be extracted—for example, as a result of traumatic fracture or infection (Fig. 30-10), possibly associated with long-term calculus formation, or because long-term (greater than 12 months) unerupted canines are causing mucosal ulceration and biting problems in horses older than 6 or 7 years. Because of the great length

Figure 30-8. This horse is having endodontic treatment of its traumatically damaged incisors (402 and 403). Exposed necrotic pulp in 402 has been removed to the level of healthy pulp, which has then been sealed with calcium hydroxide paste, and the pulp canal above has been acid etched. A bonding agent is now being applied to the sealed pulp canal.

Figure 30-9. A modern, self-curing composite filler is being inserted into the prepared pulp cavity on top of the calcium hydroxide layer to further seal off the underlying vital pulp (same horse seen in Fig. 31-8).

Figure 30-10. In this horse, which has gross caries and secondary periodontal disease of its left mandibular canine (304), a local anesthetic injection is applied into the periodontal membranes to facilitate removal of this tooth.
of their unerupted crown (up to 7 cm long), extraction of uninfected canine teeth is difficult and should never be undertaken without good reason. Extraction is performed by initially removing the vertical aspect of the lateral alveolar wall (Figs. 30-11 and 30-12) of the tooth. A dental elevator is then used to further loosen the canine tooth in the more horizontal, apical aspect of the alveolus, to allow complete extraction (Fig. 30-13). It is a difficult procedure, and firmly attached younger teeth and the apical aspect of the canine tooth may fracture during extraction. In the absence of apical infection, up to one third of the root (canine teeth are brachydont teeth) may be left in the alveolus without causing postoperative problems.

Disorders of “Wolf Teeth” (Triadan 05s)

Wolf teeth (Premolar 1, Triadan 05) are small vestigial teeth (usually 1 to 3 cm long) that are blamed for many behavioral and biting problems in horses and therefore are frequently extracted. Wolf teeth most commonly develop in the maxilla, lying in front of the 06s. If normally positioned and small, it is difficult to envisage how upper wolf teeth can interfere with the bit. However, displaced, enlarged, fractured, or unerupted (“blind”) wolf teeth with overlying painful or ulcerated mucosa may cause biting problems and may also prevent “bit seats” from being made on the rostral aspects of the upper 06s. Such wolf teeth should be extracted, as should all mandibular wolf teeth. Unless digitally loose (mainly in younger horses), wolf teeth should be extracted under sedation using subgingival local anesthesia. When extracting the more deeply embedded wolf teeth commonly found in older horses, it is better to perform infraorbital or mental nerve blocks (as described later) that will anesthetize the more relevant sensory nerves deep in the periodontal ligament.

A variety of specialized instruments (e.g., Burgess or Musgrave elevators) can be used to separate the gingiva around these teeth, and an elevator is subsequently inserted into the periodontal space to loosen the teeth (Fig. 30-14), followed by forceps extraction when adequately loosened. Large (often unerupted) wolf teeth may have to be extracted using a mucosal incision, followed by loosening them from the underlying premaxilla using an osteotome and mallet. In contrast, small mobile wolf teeth in younger horses may be extracted using forceps only. It is imperative to separate firmly attached wolf teeth from the alveolus and, most importantly, not to break them off above alveolar level, where the protruding fragment will cause more oral discomfort than was present prior to extraction. If the roots or adjacent apical

Figure 30-11. This horse had a long-term bitting problem associated with a partially erupted canine tooth (204) that caused chronic painful ulceration of the overlying mucosa. After sedation and infraorbital nerve block, an incision is being made over the ventrolateral aspect of the 204 alveolus.

Figure 30-12. After retraction of the incised mucosa, the ventrolateral aspect of the alveolar wall of 204 has been removed with a dental elevator, revealing the vertical aspect of the crown of the problematic canine (arrows).

Figure 30-13. Note the great length and the curvature of the canine tooth, which has been extracted intact. A Butler’s gag is being used.
parts of wolf teeth fracture below alveolar level during extraction, these alveoli will usually heal over fully and so should be of little concern. The greater palatine artery can be lacerated during wolf tooth extraction, and infection and tetanus can also develop after such procedures.

Disorders of the Cheek Teeth

Developmental Disorders of the Cheek Teeth

RETIRED DECIDUOUS CHEEK TEETH

Retention of the remnants of the deciduous CT ("caps") can occur in horses between 2 and 5 years of age. When loose, and especially when partially retained by their gingival attachments, they may cause oral pain, and affected horses may show quidding, biting problems, and, occasionally, loss of appetite for a couple of days. Such signs in this age group warrant a careful examination of the rostral three CT for evidence of loose deciduous CT. Loose caps should be removed using specialized cap extractors.

The prolonged retention of caps has been alleged to cause delayed eruption of permanent CT, and the development of large eruption cysts ("bumps" in 3- or 4-year-olds) under the apices of the erupting permanent CT (07s and 08s), but another study found no evidence of this. The presence of very enlarged eruption cysts, especially if unilateral, should prompt a thorough oral and, if necessary, open-mouth radiographic examination for the presence of retained deciduous CT. Additionally, standard radiographic views for evidence of apical infection should also be obtained. However, the practice of methodically removing deciduous teeth at set ages in horses results in the premature removal of some deciduous CT, exposing their underlying permanent counterparts too early. In the upper CT, this leads to loss of blood supply to the still-developing infundibular cementum, possibly leading to infundibular cemental hypoplasia (patent infundibulum) and thus predisposing the tooth to infundibular caries and possible apical infection or CT fracture later in life.

DIASTEMATA

The occlusal surfaces of all six CT are normally compressed closely together, and each CT row should function as a single grinding unit. This compression of the CT together is achieved by the action of the angled rostral and caudal CT compressing together the occlusal aspects of all six CT. Even with age, the progressively smaller reserve crowns usually remain tightly compressed at the occlusal surface (the CT taper in slightly from crown to apex). However, if spaces, or diastemata, develop between the occlusal aspects of adjacent CT, clinical problems will occur. Very severe clinical problems occur when these spaces are narrow (often only 2 to 3 mm wide) at the occlusal surface and wider at the gingival margin, a condition known as valve diastema. In some cases, CT diastemata are caused by lack of sufficient angulation of the rostral and caudal CT to provide enough compression of the occlusal surface of the six CT. In other cases, diastemata occur with apparently normal angulation, suggesting that the dental buds developed too far apart. Individual diastema can also be caused by displaced or supernumerary CT, or it may occur adjacent to overgrown CT (e.g., rostral to an overgrown lower 11 or caudal to an overgrown upper 06 that has been displaced caudally and rostrally, respectively, because of their focal overgrowths).

Food becomes impacted into these abnormal interdental spaces by the prolonged grinding of tough forage (Fig. 30-15), and this leads to progressively deeper and more painful packing of food into the sensitive periodontal spaces, which causes a secondary, malodorous periodontal infection. Diastemata can be recognized by visually (with a dental mirror or intraoral endoscope) or digitally detecting food fibers protruding between these teeth, most commonly at the gingival level. In a longer standing case, this food pocketing and periodontal disease may extend along the full width of affected teeth and extend deep into the mandible or maxilla (including into the maxillary sinuses). Evaluation of the severity and numbers of diastemata can be difficult. Oral endoscopy or intraoral mirrors, or obtaining 10- to 15-degree, latero-oblique radiographs with the horse’s mouth open, can be very useful.

Treatment of CT diastemata is difficult. Cleaning out the periodontal pockets manually (with dental picks and long...
forceps) or with pneumatic or high-pressure water instruments, and filling the periodontal defects with antibiotics and plastic impression material, gives only temporary relief unless the underlying mechanical predisposition to this food impaction is also treated. Many horses show severe clinical signs when fed hay and then improve greatly when out at grass in the summer. Likewise, feeding only a finely chopped (milled) diet, such as grass or alfalfa cubes (whose fiber length is too short to become entrapped in diastemata), often reduces or fully removes clinical signs.

In younger horses with mild developmental diastemata, provided there is sufficient angulation of their CT (as adjudged radiographically), the abnormal spaces may close when further dental eruption occurs. Such horses should not have their diastemata widened.

Currently, the best treatment for this disorder in mature horses appears to be to widen problematic diastemata—to about 6 to 8 mm wide on the occlusal surface—using a specialized burr (Powerfloat, D&B Enterprises, Inc, Calgary, Alberta, Canada). Cases should be evaluated and selected by clinical examination and possibly by open-mouth radiography. Horses to be treated should be heavily sedated and the periodontal pockets and diastemata cleared of food, the former usually causing much discomfort to the horses. During widening of diastemata, water should be sprayed over the CT being burred to prevent thermal pulpar damage. As much tooth as possible should be removed from the rostral aspect of the tooth positioned caudal to the diastema, to help avoid exposing dental pulp (Fig. 30-16). If just a single painful diastema is causing a problem, extraction of a tooth on one side of the diastema may result in complete cessation of quidding, as food will not become trapped in a wider space. Some young horses with severe, multiple diastemata and osteomyelitis of alveoli and supporting bones will be very difficult if not impossible to treat.

**ROSTRAL POSITIONING OF THE MAXILLARY CT ROWS**

A common dental abnormality in horses is a rostral positioning of the maxillary CT rows relative to their mandibular counterparts, invariably in conjunction with overjet ("parrot mouth"). This disorder eventually leads to the development of focal overgrowths of the rostral aspect of the upper 06s, which may cut the cheeks and interfere with the bit. If small, these overgrowths can be manually rasped level with a solid carbide float, but if they are large, a power tool is best to reduce them, in stages of about 5 mm at a time and a few months apart, to avoid pulpar exposure.

Similar overgrowths on the caudal aspect of 311 and 411 frequently go undetected and can lacerate the tongue and wear down the opposite CT (maxillary 11s) to gum level. There is very little room between the occlusal surfaces of the caudal maxillary and mandibular CT, especially if large overgrowths are present on these teeth. Consequently, these overgrowths are best reduced using power tools, grinding them from their medial aspect if there is not enough room to reduce them from their occlusal surface. Molar cutters and percussion guillotines (which encircle this caudal hook) can fracture these teeth, causing pulpar exposure, especially in smaller breeds (e.g., Arabian and Welsh ponies) that have marked dorsal curvature (curve of Spee) of the caudal occlusal surface of their CT. Such dental fracture and pulpar exposure may lead to life-threatening cellulitis of the mandibular and pharyngeal areas; at the very least, this necessitates CT extraction.

**DISPLACEMENTS OF THE CHEEK TEETH**

Most severe cases of equine (medial, lateral, rotatory) CT displacements are developmental and appear to be caused by overcrowding of the CT during eruption. This type of displacement is often marked and also may be bilateral. Gross dental overgrowths later develop on areas of the displaced tooth and its occlusal counterparts that are not in contact, causing soft tissue trauma. Additionally, painful food pocketing develops in diastemata that are invariably present on both sides of the displaced CT. This often causes severe and painful periodontal disease (Fig. 30-17) and even osteomyelitis, sinusitis, or oro-sinus fistula formation. Acquired CT displacements (usually medial displacements of the lower 10s and 11s) can also develop in older horses and are usually associated with lesser degrees of CT displace-
ment and overgrowth, but they still may cause painful diastemata.16

Abnormal protrusions or overgrowths on displaced CT should be removed, preferably with a power tool. Painful diastemata can be widened with a diastema burr, and these horses usually cease quidding immediately. Overgrowths on opposing CT should be extracted as repulsion of the caudally positioned (usually suborbital) and also caudally angulated reserve crown and apex is technically very difficult. In the absence of periodontal disease, 6-monthly removal of overgrowths is recommended. Extraction should be performed per os if possible, as repulsion of the caudally positioned (usually suborbital) and also caudally angulated reserve crown and apex is technically very difficult. In the absence of periodontal disease, 6-monthly removal of overgrowths is required.

SUPERNUMERARY CHEEK TEETH

Supernumerary CT (i.e., the presence of more than six cheek teeth in a row) are not uncommon in horses, usually occurring at the caudal aspect of the maxillary, and less commonly the mandibular, CT rows. These may be large constricted structures (i.e., formed from two to three fused, maldeveloped CT). Because they are sometimes large and irregularly shaped, or because of overcrowding of adjacent CT, abnormal spaces and thus periodontal food pocketing occurs between the supernumerary and adjacent teeth, with resultant pain and quidding and occasionally deeper infections.16 Additionally, if the supernumerary teeth are present in just one row (i.e., are unopposed), they later form large overgrowths. If severe periodontal disease develops, particularly if associated with sinusitis or an oro-sinus fistula, the supernumerary CT should be extracted. Extraction should be performed per os if possible, as repulsion of the caudally positioned (usually suborbital) and also caudally angulated reserve crown and apex is technically very difficult. In the absence of periodontal disease, 6-monthly removal of overgrowths on supernumerary CT is required.

Acquired Disorders of the Cheek Teeth

ACQUIRED OVERGROWTHS OF CHEEK TEETH

Feeding concentrates greatly alters the masticatory action of horses, causing them to chew with a more vertical rather than lateral mandibular action, and also for a much shorter time, than a horse that is eating forage. This restricted lateral mandibular movement predisposes horses to develop overgrowths (initially involving primarily enamel) of their CT.22 If these painful enamel overgrowths are neglected, the sharp enamel points eventually merge into a steeply angulated (e.g., 45 degrees versus the normal 10 to 15 degrees) occlusal surface, termed shearmouth or “scissor mouth”. A mechanical obstruction now additionally obstructs the normal side-to-side mandibular masticatory movements, rendering mastication even less efficient. Food stagnation and secondary periodontal disease also commonly develop. In advanced cases of dental overgrowths, undulating irregularities of the occlusal surface of the CT rows in the rostrocaudal plane (i.e., “wavemouth”) develop.

Some horses may chew very slowly, make soft slurping sounds (instead of the normal vigorous crunching sounds) when chewing forage. Some affected horses may use just one side of their mouth for chewing rather than alternating sides (and develop a sloping incisor occlusal surface—“slope mouth,” “slant mouth”), or they may hold their head in an abnormal position during chewing. Affected horses may also have abnormal head carriage, and biting problems. The prime role in equine dental care is to prevent these overgrowths from developing by routine oral examinations and effective teeth rasping. Further information on this important area is available in the literature.23

TRAUMATIC DISORDERS OF THE CT AND BARS OF THE MOUTH

In young horses, traumatic mandibular fractures inevitably cause damage to the long CT reserve crowns, which occupy much of this bone (see Chapter 103). In most cases of unilateral, nondisplaced mandibular fractures, conservative therapy (1 to 2 weeks of antibiotic therapy and feeding a soft diet, such as soaked grass cubes for 2 to 3 months) is appropriate, with the CT at the fracture site helping to stabilize the fracture, and the undamaged hemimandible acting as an effective splint. Traumatic fractures of maxillary CT are less common because of their anatomic position. Even if external sinus tracts develop after fracture of their supporting bones, it is worthwhile persevering with conservative therapy until radiographic changes (including the use of a metallic probe in any sinus tracts present) definitively confirm the presence of dental infection. Extraction of infected CT should be delayed for at least 3 months to allow mandibular or maxillary fracture healing to occur.

Bit-induced injuries to the dorsal aspect of the mandible at the interdental space (bars of mouth) can occur as a result of very excessive bit force.11,24 In most cases, a superficial periostitis or sequestration of the dorsal mandibular cortex will occur at this site. However, pathologic fractures of the mandible, mandibular osteomyelitis, and lower 06 CT infection can also occur.11,24,25 These mandibular bone injuries should be assessed radiographically and sequestered removed under sedation. The horses should be ridden with a bitless bridle for 4 to 6 weeks, and thereafter a rubber bit should be used with restraint. Exostoses may develop at the sites of bitting injuries (especially on the caudal aspect of the lower bars of mouth).26 However, some normal horses have a raised and variably sharp ridge at this site, and some also have some roughening of the mandibular cortex at the insertion of the buccinator muscles. Very large and irregular exostoses at this site may cause damage to the overlying mucosa because of bit contact, and in doing so they cause permanent biting problems. Such large bony protrusions can be removed under sedation and local anesthesia using an osteotome.26

Idiopathic fractures of the CT

Idiopathic CT fractures (i.e., CT fractures in the absence of known trauma) are common in horses.22 Most commonly, “slab” fractures occur through the two lateral pulp cavities (Fig. 30-18), usually of the upper 09s.22 Less commonly, lower CT also suffer from such fractures. The fracture site usually becomes filled with fibrous food, thus laterally displacing the smaller lateral CT fragment into the cheeks, causing buccal lacerations with subsequent quidding and biting problems. Removal of the smaller, loose fragment with CT fragment forceps (Fig. 30-19) usually resolves the clinical signs, even though radiographic and scintigraphic evidence of apical inflammation and alveolar remodeling often occur in these cases. In many cases, the remaining pulps become effectively sealed off from the fracture site...
with reparative dentine, and the remainder of the CT erupts normally. Less commonly, pulpar exposure is present in the remaining larger (medial) fragment, indicating that pulpar death has occurred, and this remaining fragment is likely to have to be removed within a year or so when it loosens, or if it causes clinical signs of apical infection.

Midline (sagittal) fractures of the maxillary CT occur less commonly than slab fractures, but the 09s are again most commonly affected. This type of fracture is believed to be secondary to advanced infundibular caries, with coalescence of two carious infundibula leading to mechanical weakening and fracture of the CT and subsequent infection of the underlying pulp and periapical aspect of the tooth. Maxillary sinusitis sometimes accompanies these types of fractures if the infection spreads outside the alveolus. If clinical signs of apical infection occur, the affected tooth should be extracted, per os if possible, even though the clinical crown is weakened. This can best be performed by cleaning out the food in the fracture site and using CT extractors to close the two fragments together, and then gently rocking the combined fragments until loose. Because of concurrent periodontal disease, extraction is usually easy (Fig. 30-20). Sinus lavage is also required if sinusitis is present. In the absence of clinical signs of apical infection, extraction of the looser fracture fragment (usually the lateral) is sufficient. The remaining, stable dental fragment should be reduced in height to prevent medial displacement during mastication. Its retention prevents drifting of adjacent CT into its space, for a few years perhaps, and also partially prevents the development of major overgrowths (“stepmouth”) on the opposite CT.

**FILLING OF CARIOUS INFUNDIBULA**

An endodontic-type treatment has been used for treating deep caries of the infundibulum, to prevent further decay and to structurally strengthen these CT, and so prevent them from fracturing and also to prevent extension of the caries into the pulp, leading to apical infection. After cleaning out food with a dental pick (Fig. 30-21) or high-pressure aerosol or water lavage, the carious cementum in the infundibula is removed using a dental drill (Fig. 30-22) or by high-pressure aerosol abrasion with fine silica or aluminium powder (Fig. 30-23) (Equine Dental System, Pacific Equine Dental Institute, El Dorado Hills, Calif). The cleaned infundibulum is then acid-etched and a bonding agent is applied (Fig. 30-24) before it is filled with a composite restorative material (Fig. 30-25) as previously described (for incisor fractures). As access to these carious infundibula (usually in

![Figure 30-18.](image1.png)

*Figure 30-18.* Intraoral view of a horse with a lateral “slab” fracture of 208. The fracture site is filled with food that has slightly displaced the larger medial portion into the hard palate and markedly displaced the thin, lateral fragment (arrows) into the cheeks, where it has caused buccal ulceration (arrowheads).

![Figure 30-19.](image2.png)

*Figure 30-19.* A lateral “slab” fracture of a maxillary cheek tooth that was readily removed with forceps. Gross caries on its medial aspect and destruction of its apical area (arrowheads) are evident.

![Figure 30-20.](image3.png)

*Figure 30-20.* This mandibular tooth had a sagittal fracture and subsequent food impaction and displacements. Both parts of the fractured (and now carious) cheek tooth were orally extracted with little difficulty (see extractor forceps marks on tooth).
the upper 09s) is difficult, it may not always be possible to fully remove all carious cement (or enamel) deep in the infundibula. Therefore, it is unclear whether this therapy can always prevent progression of caries to involvement of the adjacent pulp or apex, but it should make the affected upper CT more mechanically sound and thus help prevent sagittal fractures.

**DENTAL (ODONTOGENIC) TUMORS**

Dental tumors are rare in horses, but when present they can mimic apical infections (i.e., with the presence of maxillary and mandibular swellings that later may become much larger than the swellings commonly associated with apical infections). Additionally, these swellings do not usually develop sinus tracts, and they are firm and painless. Dental tumors include ameloblastomas, which are noncalcified epithelial tumors derived from the epithelium that forms enamel. A similar tumor, an ameloblastic odontoma, does induce calcification of adjacent mesenchymal tissues (and reciprocally of enamel epithelium) and so also contains dentine, cementum, and enamel. The appearance of these tumors can therefore vary from a noncalcified, polycystic,
fibrous-type tumor to growths containing such tissues along with calcified dental tissues.

Dental tumors also include a variety of calcified tumors from dentinal tissues (odontoma) or cement (cementoma) or more commonly combinations of all three dental components (compound odontoma or ameloblastic odontoma). These horses typically present with slowly growing, hard focal mandibular or maxillary masses that are usually very radiodense. The prognosis depends on how well defined they are from the surrounding bones to allow complete surgical excision to be performed.

**CHEEK TEETH PERIAPICAL INFECTION**

**Etiology and diagnosis**

Apical (true roots may not even be formed at the time of infection) infections of CT may occur secondary to previously discussed abnormalities, including dental fractures or descending periodontal disease (e.g., beside a diastema). However, in most cases, the etiology is not obvious, so they can be termed primary apical infections. The proposed etiologies include bloodborne infection of pulp (or anachoresis), possibly predisposed to by impaction of the rostral CT, which subsequently develop hyperemic, enlarged eruption cysts; deep infundibular caries with extension of infection from the infundibulum into the pulp cavity (maxillary CT only); and exposure of pulp on the occlusal surface (caused by an imbalance between CT wear and the formation of secondary dentine). A recently described equine CT pulp nomenclature (Fig. 30-26) can be used to identify individual pulps in mature CT. Regardless of its etiology, if an apical infection (with death of pulp) has been present for more than 6 to 12 months, the secondary dentine normally worn away on the occlusal surface by mastication is not replaced and therefore pulpar exposure occurs over all pulp horns (Fig. 30-27). Examination for pulpar exposure using a dental mirror or endoscope and a fine steel probe is a simple and valuable clinical test for dental viability that is currently rarely used (Fig. 30-28).

In the early stages, an anachoretic infection may remain confined to the apex, and all the pulp horns (or the common pulp in immature CT) may remain vital. At this early stage of infection, antibiotic treatment (e.g., 2 to 4 weeks of trimethoprim/sulphonamide) may suffice. Surgical curettage of the affected apex has also been utilized with varying success, possibly because this procedure may further compromise pulpar blood supply by damaging the apical vasculature. Later, the common pulp or some of the pulp horns may become ischemic, causing pulpar death. At this stage, dental extraction or possibly endodontic therapy is required.

Primary apical infections occur mainly in younger horses, which have long reserve crowns and largely healthy periodontal membranes. Consequently, the infection cannot drain into the oral cavity but instead spreads to the alveolus and its adjacent supporting bones. Mandibular apical infections are invariably accompanied by unilateral, painful, ventral mandibular swellings that often develop external draining tracts. Infections of the upper 06 and 07 (occasionally the 08) CT cause focal swellings of the rostral maxilla (rostrodorsal to the rostral aspect of the facial crest), which are almost pathognomonic for dental infections. Some of these horses also develop an external sinus tract or, less commonly, a tract drains into the nasal cavity. Apical infections of the caudal three maxillary CT (09s to 11s)

**Figure 30-26.** Identification of the individual pulp chambers of mature equine cheek teeth according to reference 34. The 06s (left side of figure) have six pulp horns. The 07s-10s (center of figure) have five pulp horns. The 11s (right side of figure) have six or seven horns.
usually result in a secondary maxillary sinusitis, with a chronic, malodorous, unilateral nasal discharge, but facial swelling or tracts are uncommon with this type of sinusitis. In older horses, apical infections commonly drain through the shorter periodontal membrane into the mouth, and therefore swellings of the supporting bones and sinus tract formation seldom occur.

A thorough clinical examination should be made, including intraoral examination for evidence of abnormalities, such as CT fractures; gross infundibular caries, or pulpar exposure (see Figs. 30-27 and 30-28). Radiographic evaluation of the horse should include 45-degree ventrolateral-lateral oblique projections for imaging mandibular CT apices and 30-degree dorsolateral-lateral oblique projections for imaging maxillary CT apices. The interpretation of equine dental radiographs is often difficult because of the frequent presence of overlying anatomic structures and because of combinations of lucent areas (from demineralization of apices and adjacent alveoli) and radiodense areas (from apical hypercementosis, alveolar sclerosis, and surrounding soft tissue inflammation). Interpretation is especially problematic in early apical infections in young horses where radiolucent normal eruption cysts have radiographic similarities to apical infections. If a sinus tract is present (e.g., as occurs with mandibular or rostral [06s-09s] maxillary CT infections), it is essential to obtain radiographs with a metallic probe in situ to confirm apical infection (Fig. 30-29). This procedure also provides surgical landmarks (helpful if the infected tooth is to be extracted by repulsion). Similarly, metallic markers should be placed over areas of maximal facial swelling. When available, computed tomography imaging allows these complex three-dimensional structures to be more fully assessed. Endoscopic examination of the sinuses (sinoscopy) may be helpful, as it sometimes demonstrates normal alveoli and indicates that nondental sinusitis is present. These examinations aim to definitively confirm if any of the CT are diseased and need to be extracted.

When doubt exists about whether apical infection is present, scintigraphy may provide additional evidence. If any doubt still remains, conservative therapy should be used—for example, 2 to 4 weeks of oral potentiated sulphonamides (possibly along with oral metronidazole therapy) for suspected mandibular infections and rostral (06 to 08) maxillary CT apical infections, and maxillary sinus lavage and similar antibiotic therapy for suspected caudal (09 to 11) maxillary CT apical infections. Failure to respond to this conservative therapy should prompt a further clinical and radiographic evaluation for apical infection (serial radiographs may detect subtle changes from previous radiographs). Only when definite evidence of dental infection is present should dental extraction be considered.13,33

Figure 30-27. The occlusal surface of a cheek tooth extracted because of apical infection shows pulp exposure at all five pulps, all of which contain impacted food material (arrows). One infundibulum contains a distinct vascular channel (VC), but the other has localized infundibular cemental caries (IC), which are not clinically significant in this case.

Figure 30-28. The occlusal surface of this cheek tooth (06s have six pulp horns) has intact secondary dentine over five pulp cavities but has a pulp exposure over one (pulp horn five, with needle inserted). Some minor discoloration is present in both infundibula.

Figure 30-29. This radiograph shows an apically infected mandibular cheek tooth, with thickening of the underlying mandible, that also contains a lytic track leading to its caudal root. The caudal aspect of this root has been destroyed and is thickened more dorsally. The probe inserted up the sinus tract further confirms that infection is present in this CT.
**Treatment of Disorders of the Cheek Teeth**

**EXTRACTION OF CHEEK TEETH**

Most CT apical infections occur in younger horses, and in these cases the infection is usually confined locally to the apical area, and great mechanical force is required to break down the remaining extensive healthy periodontal membranes. Consequently, extraction of a long-crowned equine cheek tooth is a major surgical procedure with many possible immediate and delayed sequelae. Oral extraction is the technique of choice for removal of most equine CT, as it can be performed in the standing horse, does not require surgery of the supporting bones, and has greatly reduced postoperative complications compared to the repulsion or buccotomy technique.

**Oral extraction of cheek teeth**

The availability of today's safe and effective sedatives and analgesics is a major reason for the revival of the oral extraction technique. Most of the instrumentation has remained unchanged for over 100 years. A prerequisite for oral extraction of equine CT is excellent chemical restraint of the horse. This can be achieved by a combination of an alpha agonist and morphine or butorphanol. A detomidine, continuous-infusion technique has also been used successfully (loading doses of 4 mg IV of detomidine and 10 mg IV of butorphanol are given followed by 2 drops per second of a drip that contains 14 mg of detomidine in 250 mL of saline). Local anesthesia of the mental and infraorbital nerves can be used—for example, the upper 06s or 07s can be anesthetized as it enters the mandibular canal and then slowly injecting 3 to 5 mL of lidocaine. The mental nerve, which is sensory to all mandibular teeth, can be anesthetized as it enters the mandibular canal on the medial aspect of the mandible and 20 to 30 mL of lidocaine is deposited at, and 1 to 2 cm dorsocaudally to, the site.

With more difficulty, the maxillary branch of the trigeminal nerve can be anesthetized as it enters the caudal aspect of the infraorbital canal. After aseptic skin preparation, a 15-cm long, 18-gauge spinal needle is “walked” up the periosteum of the medial aspect of the mandible and 20 to 30 mL of lidocaine is deposited at, and 1 to 2 cm dorsocaudally to, the site.

For oral CT extraction, the horse should be restrained in stocks with its head on a headstand or suspended in a dental head collar. At least one assistant is needed to stabilize the head and help with the extraction. A good headlight is also required, especially when extracting caudal CT, to absolutely ensure that the correct CT are being separated and that the correct tooth is subsequently removed. In many horses, the medial aspect of the upper CT contains very little exposed crown, with the gingival margin in some horses lying just a few millimeters below the occlusal surface. In such cases, a long-handled metal dental pick is used to detach the gingiva around the affected tooth to the level of the alveolar crest on the medial aspect of the tooth. This procedure normally exposes enough of the dental crown to allow CT extractors to be firmly applied on both the lateral and medial aspects of the tooth to be extracted.

A narrow-blade CT separator (molar spreaders) can now be slowly inserted into the interdental space in front of and caudal to the affected tooth (Fig. 30-30). The separator should be kept in place for about 5 minutes to excessively stretch and so damage the periodontal ligaments. A wider-blade CT separator can then be used to further stretch the periodontal ligaments. When extracting an 07, separators should not be used between the 06 and 07, in case the 06 is excessively displaced rostrally and loosened. Separators must also be cautiously used when extracting caudal CT in horses with a marked curve of Spee, because the vertical blades of the separator will not fit the nonvertical interdental spaces of such CT and may instead fracture them.

A CT extractor is then firmly attached to the crown of the diseased tooth and the CT is rocked in the horizontal plane (Fig. 30-31). After a variable period, depending on the extent and health of the periodontal membranes, a “squelching” sound is heard. Increased movement of the forceps can now be appreciated and foamy blood can be seen at the gingival margin. After 20 to 120 minutes, the tooth usually becomes digitally loose, and only at this stage should a fulcrum be placed on the occlusal surface of the tooth rostral to the infected tooth. Vertical pressure is now exerted on the forceps, drawing the affected tooth intact from the alveolus. With caudal mandibular CT, it may be safer not to attempt elevation with a fulcrum, in case this vertical force fractures the obliquely positioned teeth. Instead, the tooth should be made digitally loose and extracted in a rostrocaudal direction using manual force (Fig. 30-32). Unlike repulsed CT, the apexes of extracted CT are virtually always intact (Fig. 30-33). If no sinus tract or secondary sinusitis is present, the empty alveolus can simply be plugged with one or two swabs (containing metronidazole or iodine) (Fig. 30-34), to prevent fibrous food from being trapped in very deep alveoli...
before it granulates closed. In older horses with shallower alveoli (less than 5 cm deep), no alveolar packing is required. The alveolus should be checked 2 to 4 weeks later and the swab removed if still present. The alveolus should now also be palpated for rough areas, usually caused by sequestration of areas of alveolar cortex. Loose fragments should be digitally removed or curetted, if detected. Specialized, long-handled, right-angled alveolar curettes (Kruuse Worldwide, Marslev, Denmark) are necessary to effectively curette the more caudal alveoli. Alveoli that still have a deep, large lumen may have a swab replaced for a further 2 weeks before being similarly rechecked.

If an external sinus tract was present prior to extraction, the bone at the base of the tract can be gently curetted percutaneously and they will usually spontaneously heal within a few days. In these cases, it is advisable to seal off the oral aspect of the alveolus with dental wax or an acrylic plug and to irrigate the sinus tract with a dilute iodine solution for a couple of days.

Oral extraction of the CT can also be performed on horses with infection of the caudal maxillary CT, which have a secondary sinusitis. If the apical aspect of the alveolus digitally feels intact after CT extraction, it can simply be packed with an antibiotic-impregnated swab, as described earlier. If the alveolus appears disrupted (very rare), an acrylic plug should be inserted to prevent the development of an oro-maxillary fistula. In all cases of maxillary sinusitis caused by dental infections, a separate small (e.g., 10-mm diameter) portal should be made in the ipsilateral frontal sinus to allow postoperative lavage of the interconnecting infected maxillary sinus. The affected sinus should be lavaged twice daily, with 5 L of very dilute iodine solution for a week or so, or until the lavage fluid runs clear.

After successful oral extraction of CT by experienced surgeons, postoperative complications are rare (they occur in about 10% of cases) and are usually of a minor nature—
for example, nonhealing alveoli caused by alveolar sequestra, or localized osteitis. Most can be resolved by sequestrum removal, or alveolar curettage, using long-handled equine dental curettes and antibiotic therapy.  

Repulsion
The standard method for extracting equine CT in the late 19th and the 20th century has been CT repulsion under general anesthesia. This procedure has the expense and the inherent risks for morbidity and mortality of equine general anesthesia, and it is also associated with a high level of postoperative complications. A surgical window (e.g., 2 cm in diameter) is made using a bone saw, trephine, or chisel, adjacent to the infected apex. For mandibular CT repulsion, this site is beneath the ventral mandible (Figs. 30-35 and 30-36), and for repulsion of maxillary 06, 07, and occasionally 08 CT, it is on the dorsorostral aspect of the rostral maxillary bone. For the latter trephination, care must be taken to avoid the infraorbital canal and nerve. Larger (e.g., 5 to 6 cm square) caudal maxillary bone flaps (hinged in a dorsal direction) can be used to perform a sinusotomy (see Chapter 42), and this is preferable to making a small sinus trephine opening for repulsion of the caudal maxillary CT. Such larger windows allow a visual and digital inspection of the apices of the 09 to 11 CT and then allow their repulsion, if apical infection is confirmed. Infected apices lose the smooth, rounded, soft tissue-covered appearance of normal apices; instead, sharp edges of exposed apical enamel or the edges of alveoli are palpable, and local granulation tissue and mucosal inflammation are evident.

Intraoperative radiographs should always be obtained if there is any doubt about the site and the direction of placement of the repulsion punch (Figs. 30-37 and 30-38). Radiographs should also be obtained after the extraction, unless the surgeon is certain that the tooth has been fully repulsed. As wide a punch as possible should be used during repulsion, with offset punches most suitable for upper

Figure 30-35. This horse is having a mandibular cheek tooth repulsed under general anesthesia. Note the steel punch in a ventral mandibular site.

Figure 30-36. The direction of repulsion of the cheek teeth in a young horse.

Figure 30-37. Intraoperative radiography of a horse having a mandibular cheek tooth (CT) repulsed. This radiograph is being obtained to confirm punch positioning and angulation to prevent iatrogenic damage to adjacent CT.

Figure 30-38. This intraoperative radiograph shows the punch correctly positioned over the affected apex and also shows that it is facing in a suitable direction to effectively remove this (09) cheek tooth.
CT repulsion. Hammering a thin metal blade down the periodontal space, especially on the (flat) rostral and caudal CT margins, can greatly decrease the time and trauma necessary to repulse a cheek tooth.

After CT repulsion, it should be determined that the alveolus is free of dental or alveolar remnants by examining the extracted CT and by the use of postoperative radiographs. The oral (occlusal) aspect of the alveolus should now be fully dried and sealed with a dental wax plug (after mandibular or rostral maxillary CT repulsions), or with an acrylic plug attached to the two adjacent CT (for caudal maxillary CT repulsions). The plugs should lie below the occlusal level; otherwise they will loosen quickly with the high, continual forces of mastication. They should also not extend more than 3 to 4 cm into the alveolus, or they will delay alveolar healing. The surgical site used for repulsion of rostral maxillary or mandibular CT should be left open and irrigated (e.g., with a very dilute povidone-iodine solution) for a few days, especially if they remain purulent or malodorous. Broad-spectrum antibiotics should also be administered for at least 3 days after dental repulsions.

Complications very commonly occur after repulsion of apically infected CT from younger horses, because much mechanical damage occurs to the alveolar and supporting mandibular or maxillary bones during the repulsion. These problems include nonhealing alveoli as a result of remaining dental fragments or alveolar sequestra; localized osteomyelitis; oronasal, orofacial, and oromaxillary fistulae; mechanically preventing its oral extraction or repulsion.

Figure 30-39. This horse had 206 and 207 repulsed some years previously, leaving it with a chronic, nonresponsive oro-nasal-facial fistula. After incision of the lips for access, a sliding hard-palate flap was used to close the large oral defect.

Complications very commonly occur after repulsion of CT with gross sepsis of the apex or where there is localization of the mandibular or maxillary bones. A further technique for equine dental extraction involves the removal of the lateral alveolar plate (lateral bucottony technique) A number of workers have attempted to treat apically infected CT by use of endodontic (pulp canal) therapy. A major advantage of endodontics, if successful, is that the infected tooth is preserved and thus continues to erupt normally (at about 2 to 3 mm per year). This prevents the development of overgrowths (‘‘stepmouth’’) of the opposing CT and drifting of the adjacent CT into the site of the extracted tooth. This drifting eventually causes focal overgrowths (‘‘hooks’’) on the caudal and rostral aspects of the opposing CT row.

Removal of the lateral alveolar plate (lateral bucottony technique)

A further technique for equine dental extraction involves the removal of the lateral alveolar plate and has been used for over 100 years. It is most suitable for extraction of the rostral upper three CT, but it has been adapted for extraction of the rostral three mandibular CT by the bucottony technique and also for the more caudal mandibular CT by dissecting through the masseter muscles.

This is the most suitable technique for the rare cases of chronically (sometimes of many years’ duration) apically infected CT, where progressive, dense cement deposition has occurred around the infected apex and adjacent reserve crown, making this area and its surrounding alveolus larger than the more occlusal aspect of the alveolus and thus mechanically preventing its oral extraction or repulsion. Under general anesthesia, a surgical approach is made directly through the skin and subcutaneous tissues to the lateral wall of the affected alveolus. A horizontal incision (to reduce the risk of cutting the buccal nerves) is made in the skin and soft tissues overlying the affected mandibular CT.

The buccal nerve (and possibly the parotid duct) should be identified and isolated to avoid damage, if they cross the surgical field. A vertical incision is now made in the periosteum over the lateral aspect of the affected CT and the periosteum is reflected. Through use of a bone saw or burr, the lateral wall of the alveolus is removed. The full length of the crown of the exposed diseased tooth is then sectioned longitudinally with a diamond wheel or burr before the CT is extracted in sections.

The occlusal aspect of the alveolus is plugged with dental wax and the remaining alveolus is packed with an iodine-impregnated gauze bandage, which is gradually withdrawn through a small stab incision adjacent to the surgical site. A number of workers have attempted to treat apically infected CT by use of endodontic (pulp canal) therapy. A major advantage of endodontics, if successful, is that the infected tooth is preserved and thus continues to erupt normally (at about 2 to 3 mm per year). This prevents the development of overgrowths (‘‘stepmouth’’) of the opposing CT and drifting of the adjacent CT into the site of the extracted tooth. This drifting eventually causes focal overgrowths (‘‘hooks’’) on the caudal and rostral aspects of the opposing CT row.

Equine CT endodontic treatment has been performed mainly through the apex of the affected CT, but it is also performed via an occlusal approach (as is used in brachyodont teeth endodontics). Endodontic treatment cannot be used in CT with gross sepsis of the apex or where there is extensive periodontal disease (e.g., descending apical infections because of deep periodontal disease at a diastema). Apical endodontic therapy is performed via surgical approaches through the mandibular or maxillary bones. A
The large, common pulp (in young horses) or individual pulp horns (five pulp horns in all mature CT; except the 06s have six, and 11s have six or seven—see Fig. 30-26) are then assessed for viability and removed with barbed broaches if found to be nonvital. Any impacted vegetable material (as a result of occlusal pulp exposure) is removed and the canals are then filed using long endodontic files, until normal-appearing dentine is reached (as adjudged by the color of the filings). The pulp canal can be sterilized by irrigation with 2.5% sodium hypochlorite solution (household bleach) and then lavaged with water and air-dried. The canal lining is then etched with a phosphoric acid preparation and lavaged and dried again. The surface is subsequently coated with a dental bonding agent (some agents need to be cured by UV light) and the pulp canal is then filled, in layers, as completely as possible, with a modern, compound restorative material, some of which also need to be cured by UV light in stages. Air pockets may preclude complete filling of the occlusal aspects of some long, narrow equine CT pulp canals in mature horses.

Baker described an 84% success rate with (apical) endodontic therapy for mandibular 08s and 09s, but poor success with maxillary CT. Other workers have had poor results in trying to treat infected teeth with apical endodontic therapy, with some horses requiring two to three courses of treatment, under general anesthesia, sometimes taking over 2 hours per treatment. Such repeated and prolonged surgery under general anesthesia is costly and has safety considerations for the horse. It is believed that in younger horses, the presence of a very large common pulp cavity is one reason for the failure of this technique in this age group. Consequently, some authors advocate that endodontic treatment should be reserved for more mature teeth (e.g., CT that have been erupted for at least 3 or 4 years). Specialized training and equipment (including long drills and reamers) are required for endodontic therapy of the long equine pulp canals. Additionally, there is still debate over what is the most suitable material (e.g., modern two-part composites, self- or light-cured; amalgam or glass ionomers) for pulp canal filling in horses. Endodontic therapy offers much potential benefit in treating apical infections, but until larger studies have more fully evaluated case selection criteria, long-term efficacy, costs, and the safety of this technique, its wider role in equine dentistry remains unclear.

More recently, endodontic therapy via the oral cavity has been advocated in cases of pulp exposure on the occlusal surface of CT. However, many such horses have deeply impacted vegetable matter down their pulp canals that may be impossible to fully remove, even with use of high-pressure silicate or aluminium powder aerosols, and after completely drilling out the full occlusal surface of these canals. After cleaning, exposed pulp cavities are sealed with restorative material as previously described. If the affected canal still contains food material or if inaccessible areas of caries have not been removed, it is possible that endodontically sealing off its occlusal drainage may transform a nonclinical apical infection to one with clinical involvement of the supporting bones and sinuses. Notwithstanding these theoretical arguments against occlusal endodontic therapy, some operators have reported success with this therapy.

**ORAL CAVITY SOFT TISSUE TRAUMA**

The soft tissues of the oral cavity are susceptible to traumatic injuries by harness bits or other oral tack, sharp external objects, blows to the head, injury during recovery from general anesthesia, and iatrogenic damage during intraoral procedures—for example, dental extraction or transoral epiglottic entrapment release.54-56 The face and oral cavity soft tissues have a tremendous capacity for repair. Minor, superficial lacerations of the mucosa, lips, and tongue can heal effectively by second intention, usually within 2 weeks, without leaving a scar. Management may entail flushing of the oral cavity after meals with an antiseptic solution, warm salt water or clean water, and the use of nonsteroidal anti-inflammatory drugs. Larger wounds should be considered for surgical repair, to maintain tissue function, and for cosmesis. For these repairs, antimicrobial therapy may be needed in selected cases.

**Tongue**

Lacerations of the tongue are not uncommon and can be severe, with transverse lacerations more frequent than longitudinal ones.58-60 The free portion of the tongue is usually involved because of bit location and because this part has more exposure to the external environment. Clinical signs include oral hemorrhage, pyalism, anaptemence, anorexia, dysphagia, malodorous breath, pyrexia, and tongue protrusion from the mouth. Management of tongue lacerations is guided by the severity, duration, and location of the injury. Partial glossectomy, primary wound closure, or secondary wound healing are approaches to treatment. Surgical procedures are most easily performed on the anesthetized patient; however, the tongue can be operated on in the standing horse with effective sedation and infiltration of local anesthetic. Traction on the tongue for exposure can be achieved by placing towel clamps in the tongue caudal to the laceration or by using a gauze snare at this site, which also serves as a tourniquet.54,55,56

Partial glossectomy is reserved for cases in which the rostral tongue tissue is devitalized and minimal attachment is left between the severed section and the remaining body. Tissue color, temperature, and evidence of bleeding at an incision can be used to assess viability. Observation of fluorescence after intravenous administration of sodium fluorescein allows a more objective assessment of tissue vascularity.54 After amputation, the remaining stump is meticulously debrided of nonviable tissue. Mucosal-to-mucosal closure of the stump is not imperative53 but can be performed to aid hemostasis and hasten wound healing. Correct dorsal to ventral apposition is assisted by removing a wedge of intervening musculature and closing the created space with multiple rows of interrupted absorbable 2-0 or 0 sutures. The mucosal edges are subsequently closed with...
buried sutures of a similar size (Fig. 30-40). Involuntary loss of saliva from the mouth may be observed after amputation of a large part of the free portion of the tongue. Primary closure of severe tongue lacerations is encouraged whenever possible. The wound edges are débrided of necrotic and contaminated tissue and lavaged vigorously. A multilayer closure to eliminate dead space is recommended. To relieve tension on the closure, vertical mattress sutures are preplaced deep in the muscular body of the tongue with absorbable or nonabsorbable size 0 or 1 monofilament suture. Buried rows of simple interrupted 2-0 to 0 monofilament absorbable sutures are then used to appose the muscles, obliterating dead space. The vertical mattress sutures are tied, and the lingual mucosa is apposed with simple continuous or interrupted vertical mattress sutures (Fig. 30-41).

Second-intention wound healing for management of tongue lacerations is a viable option, particularly when economic constraints preclude surgical repair, and for chronic and less extensive lacerations. Oral lavage with a clean antiseptic solution after meals and careful attention to the horse’s ability to eat and drink are indicated. Lacerations that have healed by second intention but result in poor tongue functionality can be reconstructed using primary closure techniques after sharp débridement of scar tissue.

After lingual surgery, most horses eat normally, and temporary feeding via a nasogastric tube is rarely required. Gruels of pelleted feeds mixed with water, bran mashes, and wetted hay can be given before introducing drier feeds. Nonsteroidal anti-inflammatory drugs are administered, and antimicrobial therapy is used according to the level of tissue devitalization. Nonabsorbable sutures are removed in 2 weeks. Postoperative complications include excessive swelling of the tongue and suture dehiscence. The cosmetic appearance is usually highly acceptable.

Lips

Lip trauma occurs from protruding rigid objects in the horse’s environment, such as metal buckets, nails, bolts, and hooks, or from iatrogenic bit damage. When there is major disruption, surgery is indicated to preserve lip function and cosmetic appearance. Injuries with extensive tissue contusion and devitalization should be managed by delayed primary closure to optimize the amount of healthy tissue for suturing; otherwise, most lacerations can be repaired at presentation. General anesthesia facilitates a meticulous repair, but standing surgery is possible with regional anesthesia techniques. The wound edges are prepared routinely by sharp débridement and lavage. The lips are highly mobile tissues, and close adherence of the mucosa and skin to

Figure 30-40. Closing the tongue stump after partial glossectomy. After amputation of the severely lacerated tongue (A), a wedge of intervening musculature is removed (B). The created space is closed with multiple interrupted rows of sutures (C, D) before closing the mucosa (D, E).

Figure 30-41. Tongue laceration repair. After vigorous lavage of the wound (A) and débridement of devitalized tissues (B), the laceration is closed with multiple layers of interrupted sutures (C, D). The large vertical mattress tension-relieving sutures are placed first, deep in the tongue musculature.
underlying musculature results in excessive motion at suture lines during prehension. This leads to a high incidence of dehiscence unless techniques are employed to stabilize the repair.\textsuperscript{49,50,54}

To reduce motion on the suture lines, the margins of the skin and oral mucosa are sharply undermined for 1 to 1.5 cm from the edges of the wound. Vertical mattress 0 to 1 nonabsorbable sutures are placed rostral to the primary repair for increased support in this highly mobile area\textsuperscript{49} (Fig. 30-42). For an extensive lower lip laceration with loss of tissue, a rotational flap may be used.\textsuperscript{55} Avulsions of the lower lip should be supported with large mattress sutures passed through the mandibular symphysis. Wire or nonabsorbable suture material is threaded through holes drilled from the outside of the lip and chin to exit caudal to the incisors in the oral cavity, and stents of soft tubing or buttons are placed under the sutures on the oral and external sides.\textsuperscript{49,50} Primary closure of the lip and gingival mucosa is performed if practical.

Nonsteroidal anti-inflammatory drugs are administered, and the oral cavity is lavaged with a dilute antiseptic solution or hose water after meals. Antibiotic administration is not required in most cases. A normal diet can be offered after surgery, and feeding by nasogastric tube or esophagostomy is unnecessary.\textsuperscript{49} The stent sutures can be removed after 7 to 10 days and skin sutures after 2 weeks. Mattress sutures used for repair of avulsion injuries are removed 2 to 3 weeks postoperatively. The most common postoperative complication is dehiscence of the repair. Horses have a tendency to rub the repair site, which can be limited by muzzling or cross-tying.\textsuperscript{49}

**Cheek and Gums**

Partial-thickness labial vestibule and buccal cavity lacerations are managed by second-intention wound healing with oral lavaging after meals and nonsteroidal anti-inflammatory drugs. Large, full-thickness injuries may be reconstructed to prevent oro-cutaneous fistula development. Repairing the oral aspect of the wound is difficult because of limited space. Suturing the wound from the external side, starting with the mucosal layer, is more practical. Tension-relieving vertical mattress sutures should be used for the musculature.

**ORAL CAVITY FOREIGN BODIES**

Various types of metallic, usually linear, foreign bodies can penetrate the soft tissues of the oral cavity after inadvertent ingestion.\textsuperscript{46,56} Plant matter, such as grass awns or wood splinters, is also a frequent cause of foreign body reaction.\textsuperscript{58} External clinical signs include focal or diffuse intermandibular, retropharyngeal, and facial swelling, depending on where the foreign body has lodged or what it is migrating through. Swellings typically have increased heat, and the horse has evidence of pain to palpation of them. Often, antibiotic therapy causes a reduction in the size of the swelling but it recurs when drugs are discontinued. Ptyalism, halitosis, dysphagia, inappetence, and anorexia can be observed. Additionally, there may be a painful response and difficulty when attempts are made to open the jaw. Oral and oropharyngeal examinations (float the teeth before performing the latter) can reveal firm, painful swellings, the end of the foreign body, or ulcerated mucosal surfaces where the foreign body has penetrated the tissue, or where an abcessed site has ruptured spontaneously.

Diagnosis requires a combination of thorough history taking, external and oral examination, and imaging aids. Radiography is indispensable for metallic foreign bodies, but care must be taken not to miss a fine, short structure. Open-mouth head radiographs can prevent tongue soft tissues from being superimposed over radiodense dental elements that may conceal a subtle metallic body (Fig. 30-43). Ultrasonography is very useful to help pinpoint the exact location of a foreign body.\textsuperscript{55} Direct tongue ultrasonography may be performed in the standing, sedated horse, with a speculum in place, or when the horse is under general anesthesia. The narrow dimensions for contact of the ultrasound probe limit access to the rostral tongue body via the intermandibular space even when a microconvex head is used.

![Figure 30-42. Repair of a laceration involving the commissure of the lips. A and B, After appropriate débridement and lavage of the laceration, the skin and mucous membrane margins of the laceration are undermined 1.0 to 1.5 cm (stippled area in A). B is cross-sectional view with a skin, b, mucous membrane. Then vertical mattress sutures tied over stent material are placed through the lip musculature before closing the mucous membrane and skin layers to reduce motion at the suture lines (C, D). Extra vertical mattress sutures can be placed rostral to the repair to further stabilize the site (C).](image-url)
Once a diagnosis is established, the treatment of choice is removal of the foreign body. Surgical approaches may have to be creative. An external approach to a foreign body that has migrated into the deep part of the masseter muscle requires care to avoid trauma to facial nerve branches, parotid duct, and blood vessels in that region. Foreign bodies associated with intraoral swelling may be approached by incising the mass on the oral side and draining exudate into the mouth. Digital or instrumental exploration and débridement of the cavity can then be performed. The cavity is lavaged and allowed to heal by second intention. Lingual foreign bodies can be very awkward to reach when they have implanted or migrated into the caudal body or base of the tongue. Surgery can be associated with significant hemorrhage if large lingual vessels are invaded. An ulcerative defect on the tongue surface provides a useful starting point for exploring the necrotic tract that is associated with the path of the foreign body. A ventral approach between the hemimandibles is necessary in some cases and allows triangulation techniques to narrow down the field of exploration when a second instrument is also passed via the oral cavity into the tongue body. When necessary, the caudal body or base of the tongue can be exposed more effectively after a mandibular symphysiotomy. An oral speculum, an excellent light source, and long-handled instruments are valuable aids. The mouth should not be extended fully open for prolonged periods of time in a speculum (more than 30 to 45 minutes), to prevent muscle and temporomandibular joint soreness postoperatively. Intraoperative ultrasonographic, fluoroscopic, and radiographic guidance may be required to locate the foreign body. Oral endoscopy can aid visualization.

Surgical and necrotic tracts in the tongue are left to heal by second intention. Postoperative care may consist of a combination of oral lavaging, necrotic tract lavaging, and antibiotic and anti-inflammatory therapy. Ptyalism and tongue swelling can be a feature of the early recovery period. Soft feeds and gruels are fed after extensive tongue exploration, until the horse is more comfortable eating. The prognosis is excellent once the foreign body is removed.

**PERSISTENT LINGUAL FRENULUM**

Ventral ankyloglossia (persistent lingual frenulum) is a very rare congenital condition in foals. The tongue is unable to be protruded as normal because of a mucosal attachment between the ventral rostral free part of the tongue and the floor of the oral cavity. Difficulty with suckling may also occur. The condition is diagnosed by oral examination and is usually noted during the first routine neonatal assessment. Frenuloplasty is the treatment of choice, taking care not to incise the normal lingual frenulum. This may be performed under sedation and local anesthesia or under short-acting general anesthesia. The membrane is sharply transected with scissors. Electrocautery and laser division of the tissue are alternative approaches. With adequate release, the tongue should be easily extended from the mouth.

**ORAL CAVITY SOFT TISSUE NEOPLASIA**

Neoplasia of the oral cavity soft tissues is infrequently encountered but of considerable clinical significance when identified. The most common primary oral neoplasm is squamous cell carcinoma, affecting any of the mucosal surfaces. Other primary or metastatic tumors include melanoma, fibrosarcoma, hemangiosarcoma, lymphosarcoma, rhabdomyoma, and rhabdomyosarcoma of the tongue. Clinical signs include ptyalism, halitosis, quidding, nasal discharge with food material in it, dysphagia, anapetence, anorexia, and weight loss. Tumor invasion of local bony and soft tissues is often advanced, and regional metastasis may have already occurred before clinical signs become apparent and prompt veterinary attention. Direct visualization of the oral cavity reveals most tumors. Radiography can determine bony involvement, and nasal endoscopy can indicate soft tissue masses on the tongue base displacing the soft palate dorsal to the epiglottis. The definitive diagnosis requires biopsy and histopathologic examination. Often, submandibular lymphadenopathy in horses with oral neoplasia is caused by reactive inflammation rather than metastatic disease, so
biopsy of these lymph nodes may be negative in the presence of oral neoplasia.

Successful treatment depends on the type and size of tumor present and its accessibility. Tumors of the lips and rostral tongue are most readily resolved, as they are often noticed early and can be adequately excised or are accessible for intralesional chemotherapy and radiotherapy. Invasive squamous cell carcinomas have a high recurrence rate after surgical excision and have often metastasized by the time they are diagnosed.58,67

Complementary radiotherapy after radical surgical excision of squamous cell carcinoma may prevent or prolong time to recurrence.58 Fibrosarcomas also tend to recur after excision and are less responsive to radiation therapy. The prognosis for resolution of oral squamous cell carcinoma and fibrosarcoma is generally poor.58 Lingual rhabdomyosarcoma can be managed by surgical excision,61 but the long-term prognosis is unknown.

Neoplastic conditions that should be differentiated from tumors are focal gingival hyperplasia, epulis, and exuberant granulation tissue.62,66,69,70 These masses can appear neoplastic, but they carry a more favorable prognosis.

SALIVARY GLANDS

Anatomy

The major salivary glands in the horse are the paired parotid, mandibular (submaxillary), and polystomatus sublingual glands. There are also smaller buccal, labial, lingual, and palatine salivary glands.71 The distribution of serous and mucous cells within the salivary glands determines the nature of the saliva secreted. The parotid salivary gland secretes mainly serous fluid, whereas the mandibular and sublingual glands produce a combination of serous and mucous fluids.

The largest of the salivary glands, the parotid, is located in the retromandibular fossa between the vertical ramus of the mandible and the wing of the atlas. The rostral border reaches and may partially overlap the tempomandibular joint and the masseter muscle along the caudal border of the mandible. The caudal border extends to the wing of the first cervical vertebra. Dorsally, the gland extends to the base of the ear, and ventrally it extends into the intermandibular space. The surfaces of the parotid gland are associated with important vascular and neural structures.72 Glandular secretions are drained by multiple small ducts that converge at the rostroventral aspect of the gland and exit as the single parotid (Stensen’s) duct. The parotid duct initially passes along the lateral surface of the mandible and extends rostrolaterally around the ventral border of the mandible at the location of the easily palpable facial artery pulse. The duct ascends along the rostral edge of the masseter muscle and opens into the buccal cavity opposite the mandibular 4th premolar tooth (108, 208). A parotid papilla identifies the buccal ostium.

The mandibular salivary gland extends from the retromandibular fossa to the basioccipital bone. Most of its lateral surface is covered by the parotid salivary gland and part by the mandible, and its medial surface covers the larynx, common carotid, vagosympathetic trunk, and guttural pouch. Many small radicles unite to form a common duct that travels rostrally, ventral to the tongue. The duct opens a few centimeters rostral to the lingual frenulum, at the sublingual caruncle. The sublingual gland lies beneath the oral mucosa between the body of the tongue and the mandible. It extends from the level of the mandibular symphysis to approximately the first or second mandibular molar (09s and 10s). Sublingual ducts (about 30) open independently at small papillae on the sublingual fold.51

Disorders

Trauma

Trauma to the salivary glands is very infrequent, with lacerations or penetrating wounds occasionally occurring. Because of their superficial location, the parotid salivary gland and duct are more subject to traumatic injury than the other, more deeply located glands.

The hallmark sign of disruption of the gland or duct is the flow of saliva from the wound. This flow is accentuated when the horse is fed, and observation of the wound while offering feed to the horse provides a simple test to confirm that the discharge is saliva.

Diagnosis of duct disruption may be facilitated by catheterizing the duct via the buccal ostium, with the horse under general anesthesia, and seeing the catheter exit the wound. Locating and gaining access to the parotid papilla for retrograde catheterization usually requires a buccotomy incision at the level of the 108 (or 208).72 A second incision can be made a few centimeters rostral or caudal to the buccotomy to allow tunneling of the tubing subcutaneously to the buccotomy site. Retrograde contrast radiography can also be used to determine communication with a salivary gland in the case of a suspected salivary fistula. If there is no clear indication that a salivary duct or gland has been damaged, it is recommended that parotid wounds be left to heal by second intention.73 When the duct has been disrupted but this was not recognized at the time of injury, horses may be presented later with a chronically draining tract.74 Surgical management of salivary gland and duct trauma is fundamentally aimed at repairing the damaged structure or, alternatively, at eliminating saliva secretion. Most salivary fistulas spontaneously close eventually, so deferring treatment for a period of weeks is a worthwhile option.74

Fresh wounds of the parotid gland can be débrided and reconstructed with a multilayer closure, starting with the parotid capsule. The potential for suture material that penetrates the glandular tissue to provide a nidus for calculus formation should be considered. Open wound management and healing by second intention is an alternative for older or heavily contaminated wounds and for economic reasons, and this often allows successful healing without the development of a salivary fistula.58,73,74

Treatment of lacerated salivary ducts may also be by primary surgical closure or secondary wound healing. Primary closure of an acutely lacerated duct or a nonhealing salivary fistula is facilitated by suturing it over an intraluminal tube58,72-75 or by placing three sutures to appose the two cut ends as a triangle and suturing between the apices. Cannulation of the parotid papilla may not be practical in some cases.74 Alternatively, no. 2 nylon suture is threaded normograde through the distal lacerated duct end to the
parotid papilla. Tubing is passed via a 14- to 16-gauge needle cannula inserted through the cheek tissue externally to internally to enter the oral cavity just rostral to the parotid papilla. The tubing is then guided over the nylon suture into the duct, and the nylon and needle are removed. When the tip of the tube emerges from the lacerated duct at the wound, it is redirected into the proximal part of the duct and passed to the ventral aspect of the parotid gland. The duct is closed with fine absorbable or nonabsorbable suture (5-0 to 7-0) using a simple interrupted pattern. The external end of the tube is sutured to the side of the face, allowing for ease of later removal and the ability to check for continued patency of the duct. The need to leave the stent tube in place while the duct is healing after anastomosis, and how long to leave it are unclear. The tubing may support the suture line and prevent stricture development while maintaining saliva flow. A gauze mask can be placed over the horse’s head to help prevent premature tube removal. If anastomosis of the duct is not possible because of loss of too much intervening tissue, an interposition polytetrafluoroethylene tube graft may be successful in restoring duct continuity. Other options for salvaging salivary secretion capacity are to create a fistula from the duct to the buccal cavity proximal to the injury or alternatively perform duct translocation.

Successful chemical involution of the parotid gland was first described using Lugol’s iodine, with 1 to 2 mL injected transcutaneously into the gland at multiple sites. However, patient discomfort, severe swelling, and the potential for nasopharyngeal collapse and consequent airway obstruction make this method unacceptable today. Other agents that have been examined critically are 10% formalin, 2% chlorhexidine, and 2% and 3% silver nitrate. Of these chemicals, 10% formalin produces the least amount of necrosis and suppurative inflammation, so it is currently recommended. Water-soluble iodinated contrast material is also effective in eliminating glandular secretions. This must be considered when retrograde sialography is undertaken to investigate a draining fistula or duct atresia. If the contrast material is allowed to drain out and then the duct and gland are lavaged with sterile saline solution, this complication is less likely. When using 10% formalin, the duct is cannulated and a ligature tied to prevent leakage. Thirty-five milliliters of formalin is injected through the cannula into the gland. It is left in for 90 seconds and then allowed to drain out. The cannula is left in place for 36 hours. Cessation of salivary secretions occurs by 3 weeks. Allowed to drain out. The cannula is left in for 90 seconds and then allowed to drain out. The cannula is left in place for 36 hours. Cessation of salivary secretions occurs by 3 weeks. Cessation of salivary secretions occurs by 3 weeks. Cessation of salivary secretions occurs by 3 weeks.

**Sialoliths**

Sialoliths are hard concretions composed of calcium carbonate and organic matter that develop within a salivary duct or less commonly a gland. Plant material is often found as a nidus of the sialolith formation. Sialoliths appear smooth or slightly spiculated, and gray, yellowish, or white. They are rarely recognized but when they occur, they tend to affect older horses and the parotid duct is most commonly involved. Typically, a nonpainful, movable, firm structure is palpable on the lateral aspect of the face near the rostral end of the facial crest (Fig. 30-44). In some cases, the sialolith may be palpable orally.

Obstruction of the duct is often incomplete, and saliva may continue to pass around the sialolith. However, with more severe obstruction, backpressure may cause duct and gland distention, which is noticed as a possibly painful swelling in the intermandibular and retromandibular space. Other clinical signs, including the presence of purulent material in the mouth, reddening at the parotid papilla, mild icterus, fever, difficulty masticating, quidding, and decreased appetite, have also been reported in association with sialoliths. Sialoliths usually occur singularly. If multiple calculi are present in the same duct, a gratating sound or sensation may be heard or felt on palpation. Septic sialoadenitis is a rare occurrence in domestic animals but may precede or be a consequence of a developing sialolith. Inflammation and infection of the duct (of ascending, hematogenous, or traumatic origin) results in obstruction by exudates, desquamated cells, and mucus. This material may provide the nidus necessary for a sialolith to form. Partial obstruction of the duct by a sialolith may decrease natural clearance of secretions, resulting in stasis and facilitating proximal movement of bacteria. Diagnosis of sialolithiasis is assisted by radiographs, but soft tissue swelling can impede identification of a concretion.

Definitive treatment is by removal of the sialolith. Smaller calculi may be massaged out of the parotid papilla. If this...
is not possible, and the calculus is near the papilla, direct intraoral incision over the sialolith, leaving the wound to heal by second intention, is preferred. This approach avoids the risk of external salivary fistula development. Calculi inaccessible by the intraoral route must be removed by external longitudinal incision of the duct. This can be performed as a standing surgery with local anesthesia. Cannulation of the parotid duct via the parotid papilla can be helpful to locate the exact calculus position and then may act as a stent for suturing the duct if primary closure is performed. The entire duct and gland should be lavaged with sterile polyionic solution. Closure of the duct is with a simple interrupted or continuous pattern of fine absorbable suture material. The incision can be left to heal by second intention, and few develop fistulas. Postoperative care is similar to repair of a duct laceration or fistula. Antibiotics and lavage of the duct and gland via catheterization of the oral papilla are recommended in infected cases.

**Atresia of the Parotid Salivary Duct**

Congenital or acquired functional discontinuity of the parotid salivary duct is very rare in the horse. Proximal to the obstruction, the dilated duct is characterized by a nonpainful, tortuous, subcutaneous, fluid-filled tube that extends caudally from a point rostral to the masseter (where the obstruction often is located) along the ventral surface of the mandible to the base of the ear on the affected side (Fig. 30-45). In congenital cases, swelling is present at birth and can increase with time. Swelling may also increase temporarily when the horse is presented with food. Aspirated fluid has the consistency of saliva with an alkaline pH and an acellular, proteinaceous background. The swelling recurs after needle drainage, and occasionally saliva continues to drain into subcutaneous tissues after aspiration, setting up a severe inflammatory reaction, followed by persistent sialocele. Diagnosis is based on clinical appearance but can be confirmed with positive-contrast sialography and aspirated fluid analysis. Dilated glandular radicles are seen coalescing into a single grossly distended parotid duct that terminates distally before reaching the buccal cavity.

Treatment options include surgically creating a new buccal ostium, duct excision and proximal ligation, gland extirpation, and chemical ablation of the salivary gland. A buccal fistula is not recommended because of probable spontaneous closure and the potential for ascending contamination of the duct. In one case, removing a large portion of the distended duct and ligating individual radicles was successful. Duct ligation may not be appropriate in a chronic case, as severe dilation may not allow enough back pressure to be generated to cause atrophy of the gland and cessation of secretory activity. Chemical ablation of the gland is an economical, effective, and practical solution and is recommended for most cases. Surgical removal of the duct can be performed for cosmetic reasons after ablation of the gland, but it is a difficult procedure.

**Salivary Mucocele and Ranula**

Accumulations of saliva can occur in spaces adjacent the local gland or duct, possibly when an external wound has healed but the duct or gland continues to leak. A mucocele or sialocele refers to a pocket of saliva in a space not lined by epithelium. A ranula ("honey cyst") represents a mucocele of one of the sublingual salivary gland ducts and is seen as a bluish-tinged cyst on the floor of the mouth. Fluid aspirated from a sialocele is generally brown and mucinous with a higher concentration of calcium and potassium than is seen in other accumulations of fluid. Salivary fluid also contains amylase. Contrast sialography can determine any...
communication between the cavity and duct or gland. In some cases, complete surgical removal of the structure is appropriate. Ranulas respond well to marsupialization into the oral cavity. A catheter can be sutured in place for 2 to 3 weeks to create a permanent fistula. Marsupialization of a mucocele into the buccal cavity is less likely to be successful because of a lack of epithelial lining. Chemical ablation of the parotid gland would be effective and may be the simplest approach if this gland is known to communicate with the mucocele directly or via the duct. Later, the mucocele can be drained without expected recurrence.

**Heterotopic Salivary Tissue**

Salivary tissue found in an abnormal location is a rarely diagnosed disorder and is described as heterotopic salivary tissue. It is possible that this condition goes unrecognized more frequently than it is confirmed; for example, unclassified subclinical lateral nasopharyngeal masses seen endoscopically may be heterotopic salivary tissue. Heterotopic tissue associated with seromucoid draining tracts has been reported in the temporal region and the mid cervical region. Drainage of saliva from heterotopic tissue does not increase when the horse is presented with feed. Definitive diagnosis is by histopathology, and complete surgical removal resolves the condition. Chemical ablation of the tissue may also be performed, if the nature of the tissue can be ascertained beforehand.

**Idiopathic Parotiditis, “Grass Glands”**

Idiopathic parotiditis, or grass glands, refers to a syndrome of recurrent salivary gland swelling that occurs acutely in association with pasture turnout. Typically, the parotid salivary glands become swollen during the day while the horse is on pasture, and the swelling resolves overnight when the horse is stalled. The condition is well recognized in Europe and Australia but is uncommon in the United States. Characteristically, there is a rapid development of bilateral swelling of the parotid gland. Glandular swelling is innocuous, firm, and nonpainful, occasionally causes edema at the caudal mandible, and can be mistaken for guttural pouch disease or enlarged lymph nodes (Fig. 30-46). Once the horse is removed from pasture, the glandular swelling resolves. A pasture toxin is suspected but has not been identified. Sporadic or herd outbreaks are possible.

**Neoplasia**

The salivary glands are a rare site for neoplasia in the horse. Adenocarcinoma, acinar cell tumors, lymphomas, melanomas, and mixed cell tumors have been reported. Melanomas are commonly seen in the parotid salivary gland of gray horses and may represent a primary or metastatic tumor. Tumors in the parotid region can be identified by external swelling and are occasionally painful on palpation. Melanomas typically present as nonpainful, firm, irregular- or smooth-surfaced masses (Fig. 30-47). Diagnosis of neoplasia may require endoscopy, radiology, ultrasonography, and cytology of a fine-needle aspirate. Biopsy and histopathology are indicated for a definitive diagnosis. Treatment is often palliative, as wide surgical margins frequently fail to prevent benign mixed cell tumors, acinar tumors, or
melanomas from recurring. As previously mentioned, total parotidectomy is challenging and generally considered impractical in the horse.74 Adenocarcinomas often metastasize.94 Lymphomas can respond to radiation therapy. 96 Cimetidine may help with melanomas, 97-99 but often this treatment is not justified because they are slow growing and most have low malignancy.

TEMPOROMANDIBULAR JOINT

Anatomy

The horse has diarthrodial temporomandibular joints (TMJ) formed by the condylar process of the mandible and the articular tubercle of the temporal bone.51 Dorsal and ventral compartments are completely100,101 or incompletely102 separated by a fibrocartilaginous disc. The large dorsal compartment, referred to as the discotemporal joint, has a prominent caudolateral extension.102,103 The smaller ventral compartment, the discomandibular joint, has rostrolateral and caudolateral extensions.101,103 Fibrocartilage, rather than hyaline cartilage, covers the articular surfaces of the joint. The intra-articular disc, shaped like a slightly straightened C, ensures a congruent joint that is essential for mediolateral movement of the mandible in relation to the maxilla to provide effective grinding between the dental arcades.104 There is a close relationship between the planar angles of the TMJ (15 degrees) and the occlusal surfaces of the CT and the palatine ridges. This angular association is significant for functional mastication and bolus development for deglutition.104 The caudal margin of the TMJ is closely associated with the rostral border of the parotid salivary gland, and there may be slight dorsal overlap of the gland.102,105 Caudal and lateral ligaments support the joint but have been difficult to identify in anatomic studies.100,103

Disorders affecting the TMJ include luxation, fracture, trauma, and nonseptic and septic arthropathies.100 Reports of TMJ disorders and treatment are sporadic,104,106-110 although the literature of the past few years abounds with papers on diagnostic procedures.101-103,105 The prevalence of disease may be greater than is currently recognized, and it is likely to increase as more methods of TMJ examination are utilized.

Clinical Signs

The clinical signs of TMJ dysfunction are varied and often nonspecific. Dysphagia, quidding, inappetence, chronic weight loss, incisor malocclusion, altered range of motion and pain on manipulation of the mandible, localized pain and heat on palpation of the TMJ, localized swelling over the TMJ, muscle asymmetry, and draining fistulas may be identified (Fig. 30-48). Behavioral manifestations of TMJ pain include signs of depression, head shaking, altered head carriage, altered prehension and mastication, resistance to accepting the bit and other head tack, and abnormalities detected by the rider or driver during exercise. Trauma to the TMJ resulting in fractures or luxations results in acute pain and swelling, impaired prehension, and inability to appose the upper and lower incisors.100,104,106-109,111

Diagnosis

The history and clinical examination may raise the level of suspicion for TMJ pathology. However, synovial fluid analysis and effective imaging are important in determining a definitive diagnosis of the condition. TMJ effusion may not be grossly visible, but arthrocentesis of the dorsal joint

Figure 30-47. Parotid region of an aged Thoroughbred mare showing an irregular-surfaced, firm, nonpainful swelling (arrows) caused by melanoma development in the parotid salivary gland. Similar masses were present on the opposite side, and melanomas were visualized in this mare's guttural pouches.

Figure 30-48. A firm enlargement of the left temporomandibular joint (arrow) is present in this horse, diagnosed with a septic arthritis. Atrophy of the left masseter muscle is also apparent. The horse exhibited signs of pain when eating and when attempts were made to open its mouth.
compartment is still practical using anatomic landmarks. It is also suggested that the ventral compartment be accessed for synovial fluid collection. Intra-articular anesthesia of the TMJ with 2 to 4 mL of local anesthetic may confirm it as a source of pain; however, it must be determined whether pain alleviation indicates a primary joint condition or TMJ pain secondary to another condition such as dental disease.

Radiographs have traditionally been unrewarding in diagnosing TMJ pathology because considerable superimposition of head structures makes interpretation difficult. Oblique views provide the most useful of the limited information. Obvious joint disparity (e.g., a luxation or fracture) can be confirmed on radiographs, but bone lysis or proliferation is unlikely to be readily identified (Fig. 30-49).

Ultrasonographic examination of the TMJ provides a noninvasive method of assessing the lateral aspect of the joint capsule, and the articular disc and surfaces. A 7.5-MHz linear array transducer is used in B mode to examine the TMJ in a minimum of three transverse views. The caudolateral space, lateral middle area, and rostrolateral space are imaged. Thin articular cartilage is barely visible in aged horses but is about 3 mm thick in foals. Articular fluid is typically not seen in the normal TMJ. Any changes in the normal ultrasonographic appearance of the TMJ are indicative of pathology. Findings associated with severe degenerative joint disease of the TMJ have included irregular articular surfaces, absence of the intra-articular disc, a narrowed joint space, and a thickened fibrous capsule (Fig. 30-50).

Figure 30-49. Radiographic oblique view of the left temporomandibular joint indicating a widened and incongruent joint space (arrow) that was interpreted as evidence of subluxation. This horse is shown in Figure 30-48.

Figure 30-50. Ultrasonographic images obtained in similar planes of the left and right temporomandibular joints of the horse seen in Figure 30-48. Note a widened joint space, irregular bony margins to the mandibular condyle (short arrows), loss of definition of the fibrocartilaginous disc (long arrow), increased synovial fluid (arrowhead), and increased soft tissue thickness at the left temporomandibular joint compared with the normal right temporomandibular joint. C, mandibular condyle; T, temporal articular process; TMJ, temporomandibular joint.
Soft tissue and bone phase nuclear scintigraphy of the head are useful for confirming the TMJ as the location of an active process, but it is not specific for any one type of disorder.\textsuperscript{107,112} Computed tomography provides a method to evaluate the TMJ without superimposition of structures, and its usefulness has been reported in clinical cases.\textsuperscript{106,111} (Fig. 30-51). The disadvantages are cost, limited facilities with tomography for horses, and the need for general anesthesia. Magnetic resonance imaging also provides an excellent means to evaluate the TMJ, but it has similar disadvantages.\textsuperscript{113}

Diagnostic arthroscopy of the TMJ has been described using a 4-mm, 30-degree, forward-viewing scope.\textsuperscript{101,105} A caudodorsal approach provided the best evaluation of the lateral aspect of the dorsal compartment of the TMJ, including the articular disc. Visualization of the medial aspect of the compartment is very limited. Access to the lateral aspect of the ventral compartment is complicated by the position of the transverse facial artery and vein, but the rostrolateral area can be explored.\textsuperscript{101} Synovial villi are seen in both compartments in selected locations. An instrument portal can be created using a triangulation technique, but manipulations are restricted by the small space available, and separating articular surfaces with a probe results in too much iatrogenic damage.\textsuperscript{101} Lateral translational movement of the mandibular condyle away from the surgeon improves observation of the dorsal compartment. Fluid flow through the joint may be via an ingress-and-egress cannula or via a hypodermic needle attached to a partially filled syringe, followed by allowing back-and-forth fluid instillation and withdrawal with the syringe. Subcutaneous extravasation of fluids will occur if the joint is overdistended. Use of ultrasonography to determine the safest location of portals to avoid damaging adjacent vital structures is recommended.\textsuperscript{101}

Postoperatively, mild pain on palpation of the TMJ can be expected for 1 to 2 days, but eating should be as it was preoperatively.

**Treatment**

Treatment approaches for TMJ diseases follow the same principles used for other joints. Arthroscopic débridement, joint lavage, systemic and intra-articular antibiotics, and anti-inflammatory drugs are indicated for septic conditions of the TMJ.\textsuperscript{106} Nonseptic arthropathies may respond to anti-inflammatory drugs, applied systemically and intra-articularly.\textsuperscript{100,107} Conservative treatment of TMJ luxation is possible.\textsuperscript{110} Arthroscopic evaluation of a luxated TMJ may provide prognostic information in terms of the degree of damage to articular surfaces and joint soft tissues. Acute luxation of the TMJ can be reduced under general anesthesia, but the long-term prognosis for reduction is not known.\textsuperscript{110}

Unilateral or bilateral mandibular condylectomy may be used to treat painful and dysfunctional TMJs that have developed secondary to luxations, condylar fractures, severe arthritis, or ankylosis.\textsuperscript{108,114,115} The procedure is performed with the horse under general anesthesia and in lateral recumbency. A 6-cm horizontal skin incision is made, centered on the TMJ. Soft tissues, containing transverse facial neurovascular structures, are reflected ventrally to expose the joint capsule. The capsule is incised horizontally to expose the joint. The periosteum on the mandibular condyle is incised vertically for 2.5 cm and then elevated with a periosteal elevator both rostrally and caudally. An oscillating bone saw is used to make a 2-cm-deep, horizontal cut in the mandibular condyle, about 2.5 cm ventral to the articular margin (Fig. 30-52). An ostotome is inserted into the osteotomy and then lifted dorsally to fracture off the lateral portion of the condyle. Removal of this part of the condyle provides room to continue the osteotomy through the medial aspect of the condyle, using the oscillating bone saw. The condyle is grasped with forceps and freed from medial capsular attachments with scissors before removal. The meniscus is removed by incising its soft tissue attachments.

---

with a scalpel or scissors. A three-layer closure is performed: periosteum and joint capsule combined, the subcutaneous tissue, and the skin.

Close attention to addressing the primary problem is always paramount. Many TMJ disorders may be secondary to dental wear abnormalities, so appropriate dentistry procedures must be performed when indicated.\textsuperscript{100, 104}

REFERENCES

The clinical signs, diagnosis, and therapy of esophageal disease are specific and unlike those of the rest of the alimentary system. Clinical evaluation of the equine patient with esophageal disease includes physical, radiographic, and endoscopic examinations. Early and definitive diagnosis is paramount when dealing with esophageal injury, especially when signs of disease recur after initial treatment. Therapy of esophageal disorders often centers around conservative medical and manipulative management, with dietary alterations being a primary component of therapy. However, surgical management of esophageal disease in the equine patient has become commonplace and necessitates discussion of surgical anatomy, diagnostic and therapeutic considerations, surgical techniques, and complications.1-3

SURGICAL ANATOMY

The esophagus of adult horses varies in length from 125 to 200 cm (49 to 78 inches), depending on the size of the animal, and consists of cervical, thoracic, and abdominal parts. As it courses caudally, it deviates from a position dorsal to the trachea in the cranial one third of the neck to the left side of the mediastinal plane in the middle one third of the neck. (In a small percentage of horses, the esophagus courses to the right side of the median plane.) It comes to lie ventral to the trachea at the thoracic inlet.4 The cervical part of the equine esophagus is most accessible to surgery and makes up over 50% of the total length of the esophagus.

The wall of the esophagus is composed of four layers: a fibrous layer (tunica adventitia), muscular layers (tunicae musculares), a submucosal layer (tela submucosa), and a mucous membrane (tunica mucosa). The muscular layers are striated from the pharynx to the base of the heart, where they gradually blend into smooth muscle. As the esophagus courses caudally, its muscular layers increase in thickness, whereas the lumen diminishes. Except at the upper esophageal sphincter, the two muscular layers are arranged spirally and elliptically.5 On surgical incision, the esophageal wall separates easily into two distinct layers. The elastic inner layer, composed of mucosa and submucosa, is freely movable within the relatively inelastic outer muscular layer and adventitia (Fig. 31-1). The mucosa, which provides the greatest tensile strength on closure of an esophageal incision, is covered with stratified squamous epithelium and lies in longitudinal folds that obliterate the lumen except during deglutition. The mucosa is very heavily colonized by bacteria, and therefore surgery on this organ necessitates the use of prophylactic antimicrobial agents (Fig. 31-2).

The arterial supply to the cervical part of the esophagus originates from the carotid arteries. The thoracic and relatively short (2- to 3-cm [3/4 to 1¼-inch]) abdominal esophagus is supplied by the bronchoesophageal and gastric arteries. The vascular pattern is arcuate but segmental,

CHAPTER 31

Esophagus
John A. Stick

The clinical signs, diagnosis, and therapy of esophageal dis-
ease are specific and unlike those of the rest of the alimentary
system. Clinical evaluation of the equine patient with
esophageal disease includes physical, radiographic, and
endoscopic examinations. Early and definitive diagnosis is
paramount when dealing with esophageal injury, especially
when signs of disease recur after initial treatment. Therapy
of esophageal disorders often centers around conservative
medical and manipulative management, with dietary alter-
ations being a primary component of therapy. However,
surgical management of esophageal disease in the equine
patient has become commonplace and necessitates discus-
sion of surgical anatomy, diagnostic and therapeutic
considerations, surgical techniques, and complications.1-3

SURGICAL ANATOMY

The esophagus of adult horses varies in length from 125 to
200 cm (49 to 78 inches), depending on the size of the
animal, and consists of cervical, thoracic, and abdominal
parts. As it courses caudally, it deviates from a position
dorsal to the trachea in the cranial one third of the neck to
the left side of the median plane in the middle one third of
the neck. (In a small percentage of horses, the esophagus
courses to the right side of the median plane.) It comes to lie
ventral to the trachea at the thoracic inlet.4 The cervical part
of the equine esophagus is most accessible to surgery and
makes up over 50% of the total length of the esophagus.

The wall of the esophagus is composed of four layers: a
fibrous layer (tunica adventitia), muscular layers (tunicae
musculares), a submucosal layer (tela submucosa), and a
mucous membrane (tunica mucosa). The muscular layers
are striated from the pharynx to the base of the heart, where
they gradually blend into smooth muscle. As the esophagus
courses caudally, its muscular layers increase in thickness,
whereas the lumen diminishes. Except at the upper esopha-
gal sphincter, the two muscular layers are arranged spirally
and elliptically.5 On surgical incision, the esophageal wall
separates easily into two distinct layers. The elastic inner
layer, composed of mucosa and submucosa, is freely mov-
able within the relatively inelastic outer muscular layer and
adventitia. The mucosa, which provides the
greatest tensile strength on closure of an esophageal inci-
sion, is covered with stratified squamous epithelium and lies
in longitudinal folds that obliterate the lumen except during
deglutition. The mucosa is very heavily colonized by bac-
teria, and therefore surgery on this organ necessitates the use
of prophylactic antimicrobial agents (Fig. 31-2).

The arterial supply to the cervical part of the esophagus
originates from the carotid arteries. The thoracic and rela-
tively short (2- to 3-cm [¾- to 1½-inch]) abdominal esopha-
gus is supplied by the bronchoesophageal and gastric
arteries. The vascular pattern is arcuate but segmental,
without generous collateral circulation, necessitating careful preservation of vessels during surgery.

Innervation of the esophagus is derived from the ninth and tenth cranial nerves and the sympathetic trunk, as well as mesenteric ganglion cells within the muscle layers.

CLINICAL MANIFESTATIONS AND EVALUATION OF ESOPHAGEAL DISEASE

The obstructive disease of "choke" may be manifested by ptalism, dysphagia, coughing, and regurgitation of food, water, and saliva from the mouth and nostrils. Attempts at ingestion are often followed by odynophagia (painful swallowing), repeated extension of the head and neck, and other signs of distress or agitation. The time interval from swallowing until these signs are shown by the patient depends on the location of the lesion within the esophagus. With obstruction of the distal esophagus, odynophagia and retching may occur 10 to 12 seconds after swallowing. With proximal esophageal obstruction, the signs may be evident immediately. This occurs because the propagation speed of the equine esophagus is about 9.4 cm/sec in the proximal two thirds but only 4.6 cm/sec in the distal one third. Therefore, over an average length of 116 cm (45 1/4 inches), a bolus of food would take about 16 seconds to traverse the body of the esophagus. Intermittent signs of choke followed by periods of relief may indicate a disease other than simple feed impaction, and further diagnostic procedures are warranted. Anorexia, electrolyte imbalances, and dehydration accompany cases of long duration (see "Complications of Esophageal Surgery," p. 371). Aspiration pneumonia frequently follows esophageal obstruction, and the clinical signs may be present as early as 1 day after the onset of choke.

Physical Examination

A thorough oral examination should be performed to rule out an oral foreign body, dental disease, cleft palate, or oropharyngeal neoplasms. Observation and palpation of the neck in the area of the jugular furrows may reveal enlargement of the cervical esophagus. Simple food impaction of the cervical esophagus may be localized in this manner. Crepitation of a diffuse, firm enlargement may indicate loss of integrity of the esophageal wall. Passage of the nasogastric tube often confirms luminal obstruction and localizes the site of involvement. Gentle lavage of warm water through the tube may permit material to be flushed free of the obstruction if feed or consumption of bedding is the cause of the problem. At this time, sedation of the animal with xylazine (1.1 mg/kg IV) lowers the horse's head and prevents further aspiration. Lavage may be continued until the obstruction is relieved, and further diagnostic studies may be unnecessary. However, reobstruction indicates that other esophageal disease may be present, and the diagnosis should be pursued.

With any esophageal disease, auscultation and radiography of the thorax are indicated to monitor development of aspiration pneumonia. This complication is common when an esophageal problem is encountered.
Radiographic Evaluation

Esophagography in horses is diagnostic in most instances and should be considered a part of the complete esophageal examination in problems other than simple obstruction. A survey film is necessary to establish radiographic technique and the presence or absence of disease without contrast material (e.g., feed impaction or foreign body) (Fig. 31-3). Barium paste (85% wt/vol with water, 120 mL) given by mouth outlines the longitudinal mucosal folds of the esophagus with the lumen undistended and localizes the obstruction or any disruption of the lumen (Fig. 31-4). A feed impaction becomes coated with the barium, a complete obstruction halts barium flow at the site of the lesion (Fig. 31-5), and rupture of the esophagus permits barium to escape into surrounding soft tissues. If possible, sedation of the patient should be avoided during this procedure because it suppresses the swallowing reflex and causes barium to be held in the mouth, reducing the amount available to coat the esophagus.

Liquid barium (72% wt/vol with water, 480 mL) may be administered under pressure by a dose syringe through a cuffed nasogastric tube to prevent reflux into the pharynx (Fig. 31-6). This technique demonstrates strictures and associated prestenotic dilation of the esophagus, as well as space-occupying masses that displace the esophagus. Liquid barium (480 mL) followed by air (480 mL), delivered by dose syringe under pressure, provides a double-contrast study (Fig. 31-7), permitting examination of mucosal folds with the esophagus distended. This latter technique gives the best definition of mucosal lesions, such as circumferential mucosal ulcers after feed impaction. Although a diagnosis can often be made without using all three techniques, each technique demonstrates lesions not seen with the other two.

In the cranial cervical area, where the esophagus lies dorsal to the trachea, lesions that restrict distention of the esophageal lumen can be demonstrated with negative-contrast radiography (Fig. 31-8). A flexible endoscope can be...
used to localize the lesion and permits insufflation of the esophagus during radiography. Alternatively, air (480 mL) can be delivered by dose syringe under pressure through a cuffed nasogastric tube to achieve the same results. However, negative-contrast radiography alone does not yield much information about the caudal cervical and thoracic portions of the esophagus because of superimposition of the air density of the trachea and lungs.

Swallowing during contrast studies, when the lumen is being distended, produces false signs of esophageal stricture (Fig. 31-9). Xylazine (1.1 mg/kg IV), 5 minutes before the barium-under-pressure, double-contrast, or negative-contrast esophagogram, helps eliminate this swallow artifact by decreasing the reflex "secondary swallows" that follow luminal distention. However, if detomidine is used, false signs of megaesophagus can persist for more than 30 minutes.8

**Endoscopic Evaluation**

Esophagoscopy may better define the severity and extent of esophageal lesions diagnosed on radiography and can be used as an ancillary diagnostic aid. Additionally, endoscopic examination should always be performed when radiographic findings are not diagnostic. If the endoscope is 200 cm (78 inches) or longer, the entire esophagus may be examined, and esophageal lesions in the thorax of the adult horse undetected on radiographic examination can be diagnosed. A flexible endoscope that allows irrigation and insufflation is necessary to provide good observation of mucosal lesions and changes in luminal size.

Endoscopic examination may be performed safely on the restrained standing animal in most instances. Diagnostic observations are best made by starting with the endoscope fully inserted and the esophageal lumen insufflated, then slowly withdrawing the endoscope tip toward the horse's head. After each swallow, the endoscope should be cleared by irrigation and the esophagus dilated before further withdrawal. Several passes should be made over any area of suspected disease.

Longitudinal mucosal folds in the esophagus are normally seen when the endoscope tip is moved proximad and the esophagus is in the relaxed position (Fig. 31-10). Insufflation flattens these folds and permits observation of luminal size (Fig. 31-11). Inability to insufflate the esophagus and flatten the longitudinal mucosal folds usually indicates disease. This is noted cranial and caudal to a stricture. Transverse folds can be produced iatrogenically by moving the endoscope tip toward the stomach. When the cervical esophagus is insufflated, the outline of the trachea can often be seen through the esophageal wall. Swallowing produces changes in the lumen that give the appearance of diverticula or strictures to the untrained observer. The normal mucosa is white to light pink; reddened discolorations are evidence of mucosal disease.

The cranial aspect of the cervical esophageal sphincter is difficult to examine because the swallowing reflex is stim-
ulated repeatedly and the larynx directs the endoscope tip dorsally. Radiographic assessment of this area may be more diagnostic. Additionally, the longitudinal mucosal folds along the rest of the esophagus are absent in this area.

Frequently, the endoscopic appearance of an esophageal obstruction is obscured by saliva mixed with ingesta that collects proximal to the obstruction. This should be removed by suction through a nasogastric tube, and the endoscope should be reinserted immediately to observe the area of obstruction.

**Manometric Evaluation**

Esophageal dysfunction in humans is routinely evaluated using intraluminal pressure manometry. Manometric techniques have been developed, and reference esophageal pressure profiles have been established in healthy horses. The four functionally distinct regions of the esophagus demonstrated were cranial esophageal sphincter, caudal esophageal sphincter, and “fast” (cranial two thirds) and “slow” (caudal one third) regions in the body of the esophagus (Fig. 31-12). In some physiologic disorders of the equine esophagus, manometry may better define problems in which more conventional methods have not yielded a diagnosis. Manometry has yielded new information on clinical manifestations of esophageal obstruction and the effect of drugs used to treat it. However, the availability and technical

difficulty of manometry have limited its use as a diagnostic tool in equine practice.

Figure 31-13 outlines a systematic scheme of examination using physical, radiographic, and endoscopic findings to diagnose esophageal disorders. Alternative pathways may be used, depending on the disease, clinical signs, available diagnostic aids, and experience of the clinician. Physical examination, including passage of a nasogastric tube and esophageal lavage, and radiography yield a diagnosis for most common esophageal problems. Endoscopy allows definitive diagnosis of some anatomic disorders not observed with radiography. Manometry, cineradiography, and electromyography are seldom necessary and have not been commonly used in diagnosis of esophageal diseases.

**SURGICAL APPROACHES**

Three surgical approaches to the equine esophagus can be used. Each approach is dictated by anatomic location of the lesion and purpose of the surgery. The ventral cervical approach is best used for esophagotomy, esophagomyotomy, and resections involving the proximal third of the cervical esophagus. A ventrolateral approach is recommended for placing a feeding tube in the mid-cervical esophagus (esophagostomy) or for approaching the distal one fourth of the cervical esophagus, especially near the thoracic inlet. Thoracotomy is necessary to approach the distal half of the esophagus; the choice of intercostal space is dictated by the aim of the surgery and location of the lesion.

If the surgeon expects to invade the esophageal lumen, broad-spectrum antibiotics are indicated and should be chosen on the basis of sound surgical principles, expected complications, and recognized bacterial colonization of this organ. Before induction of anesthesia, a nasogastric tube should be passed as far into the esophagus as the surgical site (or beyond if possible) to facilitate identification of the esophagus at surgery. It also is necessary to avoid damage to the recurrent laryngeal nerve and vagosympathetic trunk, which are easily traumatized when retracting the carotid artery away from the esophagus. Owners should be advised that laryngeal hemiplegia is a common complication of esophageal surgery.

**Ventral Approach**

Surgical procedures are conducted with the animal under general anesthesia and placed in dorsal recumbency. A 10-cm-long (4 inch) skin incision permits exposure of about 6 cm (2 1/2 inches) of the esophagus. The skin and subcutaneous fascia are divided sharply using a scalpel. The paired muscles of the sternothyroid, sternohyoid, and omohyoid are separated along the midline to expose the trachea (Fig. 31-14). Blunt separation of fascia along the left side of the trachea permits identification of the esophagus containing the nasogastric tube. Retraction of the trachea to the right of the median plane and gentle sharp dissection of overlying loose adventitia expose the ventral wall of the esophagus.

---

**Figure 31-13.** Scheme of examination of esophageal disorders. Arrows outline pathways that are usually diagnostic for the conditions shown at the right.
Ventrolateral Approach

Placement of a feeding tube using the ventrolateral approach facilitates firm anchorage of the tube to the skin and permits it to lie in a comfortable position on the patient’s neck while avoiding impingement of the feeding tube on the trachea (Fig. 31-15). This approach also affords better access to the middle and distal cervical esophagus, where the ventral cervical musculature becomes more heavily developed, making the ventral approach less desirable. This surgical approach may be made with the horse standing, using local anesthesia, or with the horse in dorsal or right lateral recumbency, under general anesthesia.¹⁰

A 5-cm-long (2 inches) skin incision (for feeding tube placement) is made just ventral to the jugular vein. The sternocephalicus and brachiocephalicus muscles are separated, and the deep cervical fascia is incised to expose the

Figure 31-14. A, A 10-cm-long incision through the skin and subcutaneous fascia, which is sharply divided using the scalpel. C, A baby Balfour retractor placed through the incision allows easy access to the esophagus.
esophagus. It may be necessary to incise the cutaneous colli muscle in the distal cervical area.

**Approach to the Thoracic Esophagus**

An approach through the thoracic esophagus can be used for vascular ring anomalies (two patients in my experience, in which the left fourth or right fifth interspace was used) or when the suspected lesion can be resolved surgically without entering the esophageal lumen. A 5-month-old foal was successfully treated for an intrathoracic esophageal stricture with esophagomyotomy through the eighth intercostal space, and an intrathoracic esophageal pulsion diverticulum was resected in a 7-month-old foal.

The patient is placed in right lateral recumbency under general anesthesia and positive-pressure ventilation is used. The skin, subcutaneous tissue, cutaneous trunci, serratus ventralis, and latissimus dorsi are sharply divided. A subperiosteal rib resection has been described. However, in my experience, this is not necessary in foals, because rib retractors provide adequate exposure.

**MANAGEMENT OF ESOPHAGEAL DISORDERS**

**Impaction**

The most common type of obstructive esophageal disease is impaction with ingesta or bedding. It can occur in the normal esophagus of a gluttonous animal and has a typical radiographic appearance (Fig. 31-16). Nasogastric tube passage and gentle warm water lavage are usually successful for an intrathoracic esophageal stricture with esophagomyotomy through the eighth intercostal space, and an intrathoracic esophageal pulsion diverticulum was resected in a 7-month-old foal by resecting the left eighth rib.

The patient is placed in right lateral recumbency under general anesthesia and positive-pressure ventilation is used. The skin, subcutaneous tissue, cutaneous trunci, serratus ventralis, and latissimus dorsi are sharply divided. A subperiosteal rib resection has been described. However, in my experience, this is not necessary in foals, because rib retractors provide adequate exposure.

The patient is placed in right lateral recumbency under general anesthesia and positive-pressure ventilation is used. The skin, subcutaneous tissue, cutaneous trunci, serratus ventralis, and latissimus dorsi are sharply divided. A subperiosteal rib resection has been described. However, in my experience, this is not necessary in foals, because rib retractors provide adequate exposure.

**MANAGEMENT OF ESOPHAGEAL DISORDERS**

**Impaction**

The most common type of obstructive esophageal disease is impaction with ingesta or bedding. It can occur in the normal esophagus of a gluttonous animal and has a typical radiographic appearance (Fig. 31-16). Nasogastric tube passage and gentle warm water lavage are usually successful for an intrathoracic esophageal stricture with esophagomyotomy through the eighth intercostal space, and an intrathoracic esophageal pulsion diverticulum was resected in a 7-month-old foal by resecting the left eighth rib.

The patient is placed in right lateral recumbency under general anesthesia and positive-pressure ventilation is used. The skin, subcutaneous tissue, cutaneous trunci, serratus ventralis, and latissimus dorsi are sharply divided. A subperiosteal rib resection has been described. However, in my experience, this is not necessary in foals, because rib retractors provide adequate exposure.

External massage and to-and-fro movement of the water resolve most impactions. If this technique is not successful, the animal should be muzzled to prevent food and water intake and left alone for 8 to 12 hours, and the treatment should then be repeated. Frequently, the initial treatment softens the impaction and it becomes dislodged by swallowing or is easily relieved by a second treatment. Some clinicians claim that atropinization (0.02 mg/kg) for a horse with esophageal impaction aids dissolution of the impaction by promoting esophageal relaxation and reduces salivary secretions that might otherwise be inhaled. The effect of acepromazine on esophageal relaxation is supported in one experimental study. However, oxytocin administered intravenously (at 0.11 and 0.2 IU/kg) results in short-term significant relaxation of esophageal musculature in experiments, and it has become popular as an adjunct treatment for esophageal impaction. Because xylazine has similar effects, these drugs could be used together to reduce the tone of the esophageal musculature, allowing passage of the obstructions with reduced risk of esophageal injury.

Refractory cases or intractable horses may benefit from general anesthesia and water lavage under pressure. This method has the advantages of providing some relaxation of the esophageal musculature, reducing the chances of aspiration (because the horse’s head is lowered), and decreasing the risk of esophageal perforation with the tube in an intractable horse. Gentle manipulation is mandatory with this technique to avoid rupture of the esophagus. Impactions that do not respond to conservative therapy should be definitively identified by radiographic and endoscopic examination and, if amenable, relieved by longitudinal esophagotomy (see “Foreign Body,” next). Surgery is preferable to repeated trauma of the esophagus through attempts to relieve the obstruction with a nasogastric tube. Use of the nasogastric tube as a probang is not recommended and can result in severe trauma to the larynx and esophagus. Cervical esophagotomy can be performed with the horse standing or under general anesthesia, and obstructions can be lavaged through the incision if necessary.

One aftermath of simple impaction is fusiform dilation of the esophagus that predisposes to reobstruction (Fig. 31-17). This condition resolves in 24 to 48 hours, provided the dilation is kept free of ingesta. Food should be withheld.
or only small quantities of a soft diet fed for 2 days after an episode of choke to permit the lumen to resume its normal diameter. Glucose–electrolyte solutions for drinking should be provided in addition to fresh water so the electrolyte abnormalities secondary to salivary loss can be compensated.

Broad-spectrum antimicrobial therapy is indicated for 5 to 7 days because the risk of aspiration pneumonia is high after choke. If pneumonia is not the major limiting factor in this disease, simple obstruction has a favorable prognosis.

When an obstruction has been present for several days or is refractory to initial treatment, examination using radiography or endoscopy is warranted after the obstruction has been relieved. Circumferential mucosal ulceration is not uncommon in these cases and can result in esophageal stricture.

**Foreign Body**

Small pieces of wood, wire, fishing tackle, and medication boluses can become esophageal foreign bodies in horses.\textsuperscript{16,17} They often perforate the esophageal wall, resulting in phlegmon or abscessation (Fig. 31-18). The swelling that accompanies these conditions usually obliterates the esophageal lumen and results in impaction. Diagnosis is made by radiography or esophagoscopy.

Retrieval of small sharp foreign bodies under endoscopic guidance is possible but difficult; general anesthesia is recommended to prevent the swallowing movements during manipulation that may produce pain and further esophageal trauma. It is necessary to relieve the impaction before attempting this method of treatment. Blunt or round foreign bodies may be treated similar to feed impactions. Although the nasogastric tube may be used as a probe to push the object into the stomach, the risk of perforation is great. Gentle manipulation is mandatory to avoid rupture. Additionally, this technique has the risk of moving the foreign body from the cervical region only to have it lodge in the thorax, a more inaccessible site. Longitudinal esophagotomy with primary closure results in minimal complications when performed in a region of normal esophagus and has become the accepted method of removing a foreign body.\textsuperscript{18,19}

**Esophagotomy**

Surgery is preferred to manipulations that induce further esophageal trauma. Passage of a nasogastric tube as far as the foreign body (or beyond, if possible) facilitates identification of the esophagus during surgery. General anesthesia is preferred if closure is to be attempted. The patient should be placed in dorsal recumbency, and the skin of the ventral surface of the neck is prepared and draped for aseptic surgery. A 10-cm (4-inch) skin incision is made. Care should be taken to preserve the small vessels that supply the esophagus. Elevation of the esophagus from its bed of adventitia should be avoided. The left carotid sheath, containing the carotid artery and vagus and recurrent laryngeal nerves, should be retracted laterally. Pediatric-size Balfour abdominal retractors aid exposure to the esophagus, which then can be sharply incised through the muscle, submucosa, and mucosa cranial to, caudal to, or directly over the foreign body (Fig. 31-19). Where the incision is made into the esophagus depends on the mobility of the foreign body within the lumen and the amount of swelling in and compromise to the esophageal wall.

After removal of the foreign body, if the esophagus has a normal appearance in the area of the incision, closure should be completed using a simple-continuous suture of 3-0 polypropylene suture material with the knots tied in the lumen (see Fig. 31-19). Esophageal musculature may be apposed with simple-interrupted sutures of 3-0 absorbable or monofilament nonabsorbable suture material, at the surgeon’s preference. Muscular layers, subcutaneous tissue, and skin may be apposed with 0 suture material in a simple-interrupted pattern. A polyethylene drain with an outer diameter of 0.63 cm (\(\frac{1}{4}\) inch) is placed beside the esophagus and exits ventral to the skin incision through a small stab wound. This drain is maintained under constant suction for 48 hours to remove serum and blood from the surgical site.
and to provide early detection of salivary leakage should dehiscence occur.

Postoperatively, feed should be withheld for 48 hours. Parenteral administration of electrolyte solution, the composition of which depends on the horse's acid–base and hydration status, may be used to maintain hydration. Small quantities of pelleted feed in a slurry should be fed over the next 8 days before normal feeding can be resumed. Most esophagostomy incisions heal by first intention, and the intraluminal suture will slough into the lumen within 60 days (Fig. 31-20).

If removal of the foreign body is necessary through an obviously diseased segment of the esophagus, the incision may be closed and an esophagostomy tube placed through a separate incision closer to the stomach or directly into the esophagotomy incision (see “Esophagostomy,” later).

Feeding of a complete pelleted diet through the esophagostomy tube can begin immediately after surgery. Particular attention to the patient's water and electrolyte balance is necessary when closure of the esophagus is not possible20 (see “Acid–Base and Electrolyte Alterations,” p. 372).

**Ulceration and Esophagitis**

Mucosal ulceration and esophagitis commonly occur secondary to longstanding impactions. Longitudinal mucosal ulcers can be produced from impactions; more frequently, circumferential ulcerations occur. Other causes of esophageal ulceration in foals include phenylbutazone toxicity, in which generalized gastrointestinal mucosal disease is a feature, and severe gastroduodenal ulcer disease that produces secondary reflux esophagitis. Diagnosis of esophageal ulceration is best made by endoscopy (Fig. 31-21), although contrast radiography frequently defines the margins of the ulcer (see Fig. 31-7).

Conservative management should be instituted to minimize trauma to the mucosa, reduce inflammation, and control infection. A low-bulk, minimally abrasive diet (mash), nonsteroidal anti-inflammatory drugs (NSAIDs) (only if they are not implicated as causative agents), and broad-spectrum antimicrobial therapy are indicated. Because this diet results in hunger, the patient should be muzzled between feedings, or all bedding should be removed from the stall to avoid ingestion of straw or wood chips. Reexamination is recommended every 10 to 14 days. Stricture (see later) may occur within 30 days of the original insult, when the circumferential ulcer is more than 2.5 cm (1 inch) long.21 Longitudinal mucosal ulcers (especially if they are not extensive and are localized to one area of the esophagus) and circumferential ulcers less than 2 cm (⅜ inch) long usually heal without stricture.

**Rupture, Perforations, and Lacerations**

Rupture of the esophagus can occur secondary to longstanding obturation, repeated or aggressive nasogastric tube passage, foreign body perforation, external trauma to the
Esophagostomy

Cervical esophagostomy is an excellent method of extraoral alimentation that avoids the discomfort and irritation of the indwelling nasogastric tube. An additional advantage is avoidance of deleterious influences on healing of an esophageal wound by an intraluminal tube located in the immediate region.27 To use this advantage, the esophagostomy should be placed distal to the area of esophageal injury. The surgery can be performed with the horse in lateral recumbency under general anesthesia or standing under mild tranquilization and local anesthesia. Passage of a nasogastric tube facilitates identification of the esophagus at surgery.

The skin over the left jugular furrow is prepared for surgery in the desired area. The esophagus is occasionally located on the right side of the trachea and should be approached over the right jugular furrow in those horses. A 5-cm (2-inch) skin incision is made ventral to the vein. The esophagus is sharply incised longitudinally for 3 cm (1⅛ inches) down to the indwelling nasogastric tube. The nasogastric tube is removed, and a polyethylene nasogastric tube (with an outer diameter of 14 to 24 mm [1⅛ to 1 inch]) is placed into the stomach through the esophagostomy. Failure to place the tube into the stomach allows easy dislodgement. Care should be taken to ensure that the end of the tube is placed into both the elastic inner layer and the inelastic outer muscle layer of the esophagus. Difficulty in tube placement is usually an indication that the incision in the muscle layer is inadequate to accommodate the diameter of the tube. Sutures can be placed in the mucosa to form a seal around the tube but probably are unnecessary because they do not prevent leakage of saliva. The tube should be secured firmly, first with butterfly tape bandages sutured to the skin (see Fig. 31-15) and then with elastic tape bandages. Tubes of large diameter are preferred to avoid plugging with ingesta during feeding. They should be capped between feedings and flushed with water at the end of each feeding to maintain patency.

Esophagostomy tubes should remain in place for a minimum of 7 to 10 days to permit granulation tissue to form a true stoma (Fig. 31-25). A longer period is necessary for cervical area (usually a kick), or extension of infection from surrounding strictures.22-26 Cervical swelling usually prevents successful passage of a nasogastric tube, even after irrigation of the esophagus with water. Swallowed air escapes from the rupture and causes subcutaneous emphysema; this can be recognized on radiographs (see Fig. 31-18). Positive-contrast techniques demonstrate escape of barium into surrounding tissues (Fig. 31-22).

Ruptures that cannot drain to the outside result in leakage of saliva and ingesta into tissues of the neck, resulting in severe infection and phlegmon. Ruptures or perforations that allow escape of saliva and ingesta through the skin are less likely to cause systemic illness and extension of infection into the thorax. Early establishment of drainage, preferably on the ventral midline, is necessary with all ruptures of the esophagus to avoid mediastinitis, pleuritis, and even sepsis (Fig. 31-23). This should be followed with daily lavage.

Perforation or lacerations of the esophagus accompanied by minimal escape of saliva and ingesta can be repaired using the technique described for esophagotomy. Drainage and the feeding regimen used after esophagotomy should be employed. Secure closure of a ruptured or perforated defect is usually possible only in patients operated on shortly after the perforation has occurred (within 12 hours). In early cases, when esophageal tissues are too damaged to hold sutures or when infection or contamination with ingesta has already occurred, some means of draining the esophageal contents to the outside must be provided. The patient should receive systemic antibiotics and water; electrolyte and nutritional requirements should be met by tube feeding. In some cases, the feeding tube can be placed through the site of rupture into the stomach (Fig. 31-24). An alternative method of feeding that allows spontaneous healing of the rupture or successful repair of the rupture when edema and infection have been controlled is an esophagostomy performed distal to the rupture (closer to the stomach).

Figure 31-21. Endoscopic appearance of esophagitis with circumferential ulceration 24 hours after feed impaction. A stricture subsequently formed but responded to medical management.

Figure 31-22. Barium swallow in a horse with a penetrating foreign body (wire) shows swallowed air and barium that has escaped into the periesophageal tissue. (Same horse as in Fig. 31-18.)
Figure 31-23. A, Establishment of a ventral drainage following esophageal rupture in which multiple incisions needed to be made to drain food material from the cranial pectoral area. B, Daily lavage with copious amounts of water through the incisions shows the communication between the caudal cervical esophageal incisions and incisions in the pectoral area and caudal chest area behind the elbow.

Figure 31-24. A, Electrolyte nutritional requirements can be met by placing the feeding tube through the site of esophageal rupture. B, Slurry made of complete pelleted feed is used to meet this requirement.
if the tube is placed in the area of a rupture or perforation. When the tube is removed, normal feeding may be resumed. A large portion of swallowed feed may be lost through the stoma when the patient is fed from the ground (Fig. 31-26). When feed is placed at the height of the withers, however, less of the bolus is lost through the stoma with each swallow. The stoma heals spontaneously after the tube is removed, and fistula formation is rare (Fig. 31-27).

However, complications of this form of alimentation are well documented and can result in death. Early detection and ventral drainage of infections that dissect along the trachea and esophagus are vital for a successful outcome. Patients should be maintained on antimicrobial therapy until a mature stoma develops (7 to 10 days).

Resection of the esophagus after rupture is warranted if the muscular layer is obviously necrotic and does not act as a tube along which the mucosa may regenerate, and if the proximal and distal segments of the esophagus can be anastomosed without undue tension (see “Partial Resection” and “Resection and Anastomosis,” pp. 365 and 366). Few ruptures of the esophagus requiring resection occur without necrotizing cellulitis. Usually a delay in repair is necessary to permit acute inflammation to subside before surgery. During this period, the patient may be accommodated with a change in diet and tube feeding.

**Stricture**

Narrowing of the esophageal lumen because of stricture formation is usually an annular lesion and can be classified into the following three types, depending on the anatomic location of induration and fibrosis: (1) mural lesions that involve only the adventitia and muscularis, (2) esophageal rings or webs that involve only the mucosa and submucosa, and (3) annular stenosis that involves all layers of the esophageal wall. Stricture of the esophagus may be acquired as a result of external or internal trauma to the esophageal walls (especially after impactions that produce circumferential ulceration), leakage of saliva or dehiscence after surgery, or external compression by or attachment to adjacent structures. In most instances, strictures are less likely to occur when traumatic insults involve only a portion of the circumference of the esophagus. For this reason, mobiliza-
tion of the esophagus from its fascial attachments during surgery should be avoided when possible.

Strictures usually impede complete passage of the nasogastric tube and are best demonstrated by positive-pressure contrast esophagograms (Fig. 31-28). Conservative management of a stricture is aimed at dilation of the stenotic segment. Bougienage or pneumatic or hydrostatic dilators have limited practical value in adult horses because of the inaccessibility of special equipment and the chronicity of the problem. There is a report describing resolution of an esophageal stricture in a 1-month-old colt using a balloon dilation procedure. However, early lesions, such as postsurgical strictures or those following circumferential ulceration, can be dilated with the frequent feeding of small quantities of soft food over a period of several months. In seven horses that developed stricture after esophageal impaction, observation over 2 months revealed that the esophageal lumen was maximally reduced (strictured) 30 days after circumferential ulceration was observed (Fig. 31-29), after which lumen diameter increased to normal by 60 days. This also has been documented after experimental resection and anastomosis and has been observed in a series of cases involving foals. Therefore, a low-bulk diet and anti-inflammatory and antimicrobial therapy should be used, and surgical intervention should be delayed for 60 days after the original insult. It is important to impress on horse owners that several episodes of choke may occur up to 40 days after the original obstruction.

Strictures more than 60 days old have usually matured to the point where the cicatrix is too firm to yield to dilation by this method and therefore may be classified as chronic (Fig. 31-30). Chronic strictures of the esophagus may be corrected by esophagomyotomy, partial or complete resection and anastomosis, or patch grafting. Complications may occur with any of these surgical treatments, and the surgeon should take care to pick the most conservative therapy that will meet the aim of treatment. Leakage of luminal contents and reformation of the stricture requiring prolonged medical management are to be expected after resection and patch grafting. Strictures that are mural in origin respond to myotomy and have the best prognosis for recovery without

![Figure 31-28](image1)

restricture. Three successful reports appear in the literature; I have had similar experience with five other horses. The surgery should be performed with the horse under general anesthesia, with a nasogastric tube passed to the level of the stricture to permit easy identification of the involved area.

**Esophagomyotomy**

The esophagus is incised longitudinally to the level of the mucosa, through the stricture, and 1 cm (\(\frac{1}{2}\) inch) distal and proximal to it (Fig. 31-31, A). The nasogastric tube may be passed through the stenotic area at this point. From this single incision, the muscularis is separated by sharp dissection from the mucosa around the entire circumference of the esophagus (see Fig. 31-31, B). When the mucosa is freed in this manner, removal of a portion of the muscularis or multiple myotomy incisions are seldom necessary. The myotomy is not sutured (see Fig. 31-31, C), and the approach incision is closed and drained in a routine manner. If the mucosa is opened inadvertently, it should be closed immediately with 3-0 polypropylene sutures in a simple-continuous pattern. Postoperatively, feeding small but frequent quantities of soft feed may be necessary if a prestenotic dilation was present before surgery. When this dilation is no longer evident radiographically, normal feeding may be resumed.

Recurrence of postsurgical cicatricial stricture is slow to develop, with clinical signs occurring weeks or months after the operation. Conservative treatment (changing from hay to a complete pelleted diet) may be all that is necessary to resolve recurrent obstructions. A postsurgical stricture seen long after the original operation usually is the result of a mature nonresilient cicatrix and may not respond to dilation. If surgery is necessary, the surgeon should not hesitate to perform a second esophagomyotomy; however, performing another surgery in a stenotic area of the esophagus before allowing the acute inflammation of the previous surgery to subside greatly increases the propensity for restricture. If such is the case, a more hazardous procedure may have to be selected eventually to correct the problem.

**Partial Resection**

Longitudinal esophagomyotomy combined with mucosal resection provides relief of stricture caused by esophageal rings or webs or annular stenosis of all muscle layers. Performed under general anesthesia, the procedure is indicated when the cicatrix involves the mucosa and prevents passage of a nasogastric tube after myotomy. The esophagus is exposed and incised as described previously for esophagomyotomy. A longitudinal incision is made through the mucosa long enough to permit identification of the diseased segment (Fig. 31-32, A). The mucosal scar is separated by sharp dissection from normal or diseased muscle layer. Circumferential incisions are made at the proximal and distal edges of the mucosal cicatrix and it is removed, leaving the muscular tube intact (see Fig. 31-32, B).

If cut edges of the mucosa can be brought into apposition without undue tension, they are apposed by three equally spaced 3-0 polypropylene simple-continuous sutures with the knots tied in the lumen (see Fig. 31-32, C). When mucosal rings or webs are the cause of stenosis, the normal esophageal muscle should be apposed over the mucosal anastomosis (see Fig. 31-32, D), but in the case of an annular stenosis that involves the entire esophageal wall, the muscularis should not be sutured. A drain is placed next to the esophagus, and the approach incision is closed. If space permits, tube feeding through an esophagostomy placed through a separate incision distal to the stricture is ideal. When this is not possible, frequent feeding of small quantities of soft food may begin 48 hours after surgery and should be continued for 10 days before normal roughage is offered to the patient.

When the stricture is extensive and the mucosa cannot be sutured, regeneration within the muscle tube occurs readily. The muscularis may be sutured if it is healthy, or it may be left open if only scar tissue remains. Spontaneous healing is aided if esophagostomy tube feeding (located closer to the stomach than the operative site) is used. When the stricture is located too close to the thoracic inlet to permit placement of a separate esophagostomy incision, the tube

---

**Figure 31-31.** A, Esophagomyotomy: longitudinal incision of the outer layer of the esophageal wall. B, Elevation and separation of the outer (muscularis and adventitia) and inner (mucosa and submucosa) layers of the esophageal wall to complete the esophagomyotomy. C, The muscularis and adventitia are not sutured.
may be inserted directly through the stricture site. Recurrence of stricture after this procedure may be an indication for esophagomyotomy or an esophagostomy tube placed through the stricture.

Resection and Anastomosis

Complete resection and anastomosis should be reserved for rupture of the esophagus in which the muscularis is not viable. The esophagus is exposed as described previously. The area to be resected and several centimeters of normal esophagus distal and proximal to it are mobilized. Umbilical tape or rubber drain tubing (0.63 cm [1/4 inch]) is placed around the esophagus and held in place with hemostatic forceps to occlude the lumen a convenient distance from the area to be resected. Crushing clamps of any type should not be used on the esophagus. A point is selected proximal to the diseased segment, where the esophagus is sharply transected, leaving healthy tissue for closure. This procedure is repeated distally and the diseased portion is removed. The mucosal-submucosal layer is apposed with 3-0 simple-interrupted monofilament nonabsorbable polypropylene sutures placed about 3 cm (11/2 inch) from the cut edge, 2 to 3 mm (1/12 to 1/4 inch) apart, with the knots tied in the lumen. Tension of the sutures is adequate to form a tight seal without interference of the blood supply.

The esophageal muscle is apposed with interrupted horizontal mattress sutures of 2-0 polydioxanone or monofilament nonabsorbable suture material. The muscle layer has limited elasticity and, if necessary, a relief incision in the form of a circular myotomy 4 to 5 cm (11/2 to 2 inches) proximal or distal to the anastomosis can decrease tension on the repair. The approach incision is closed as described previously.

Alternative successful methods of closure have been described, but postoperative management is a major determinant of the outcome of this procedure, regardless of closure technique. Prevention of undue tension on the anastomosis by use of a standing martingale and special feeding regimen is necessary (Fig. 31-33). If oral alimentation is elected, soft foods should be given only after 48 hours and until endoscopic or radiographic evaluation of the surgery shows primary healing has occurred. Esophagostomy is the preferred method of feeding, if possible. An extensive cervical esophageal stricture produced by annular stenosis of the entire wall may preclude successful repair by techniques described previously. The diameter of the equine esophageal lumen can be increased by using a patch graft of the sternocephalicus muscle.

Patch Grafting

Antibiotics should be given preoperatively and maintained for 6 to 10 days after surgery. With the horse under general anesthesia, a ventral midline or lateral approach to the esophagus is made and, depending on location of the defect and the approach used, the brachiocephalicus and sternocephalicus muscles serve as donors for the graft. With a nasogastric tube passed to the level of the stenosis, a longitudinal incision is made through the muscularis from a point 3 cm (11/4 inch) distal to and extending 3 cm proximal to the stricture. The mucosa and submucosa are sharply incised as the nasogastric tube is passed into the stomach. A caudal portion of the muscle belly of the brachiocephalicus or sternocephalicus is mobilized by blind separation of muscle fibers. The strip of muscle should maintain its proximal and distal attachments and should be freely movable so as not to exert tension on the closure when the patient’s head and neck are moved. The graft should be wide enough to appreciably increase the lumen of the esophagus.

![Figure 31-32. Partial resection and anastomosis. After longitudinal incision of the outer layer (A), the inner layer is resected (B) and, when possible, closed transversely using several simple-continuous sutures (C). The outer layer is then closed with interrupted sutures (D).](image)

![Figure 31-33. When complete resection anastomosis is performed, undue tension frequently results in dehiscence. Undue tension on the anastomosis can be prevented by using a standing Martingale, as shown, which prevents extension of the head and neck.](image)
The edges of the mucosa and submucosa are sutured to the muscle graft using 3-0 polypropylene interrupted through-and-through mattress sutures, and the edges of the muscularis are sutured to the graft with 3-0 simple-interrupted sutures of monofilament polypropylene. Preplacement of mattress sutures and closure of both layers on one side of the esophageal defect at a time facilitate repair. The nasogastric tube should be removed before the second edge is closed. Suction drains are placed next to the esophagus, and the approach incision is closed.

Postoperatively, extraoral alimentation is preferred for 10 days (by esophagostomy, if space allows, or intravenous feeding), but soft foods may be given per os as early as 48 hours if salivary leaking has not occurred. An indwelling nasogastric tube provides a stimulus for salivation and increases the incidence of fistula formation.

**Fistula**

Fistulae of the esophagus result from causes previously described for ruptures and may be treated similarly. However, small fistulae may be a diagnostic challenge. Occasionally, they may be observed endoscopically (Fig. 31-34). More frequently, findings of endoscopic examinations and barium swallow esophagograms are normal. Esophageal fistulae should be included in the differential diagnosis when cervical swelling, fever, and dysphagia are present; a nasogastric tube can be passed to the stomach; and endoscopic findings are normal. Contrast radiography, using liquid barium administered under pressure, best demonstrates the lesion (Fig. 31-35). When ventral drainage has been established, fistulae almost always heal spontaneously. During this time, food and water may be expelled through the cloaca (Fig. 31-36). Large fistulas can extrude copious amounts of masticated food and saliva. Elevating the food and water sources will decrease the amount lost. If healing does not occur, resection of the sinus tract and closure of the esophageal stoma may be necessary (Fig. 31-37). Closure of the esophageal defect should be performed as for esophagotomy.

**Diverticulum**

In horses, diverticula of the esophagus only occasionally cause esophageal dysfunction. Usually they are acquired lesions that result from contraction of periesophageal fibrous scar tissue, causing outward traction and tenting of all layers of the esophageal wall (traction, or true diverticulum). Or they can occur from protrusion of mucosa and submucosa through a defect in the esophageal muscularis (pulsion, or false diverticulum) (Fig. 31-38).

A traction diverticulum commonly develops at the site of a healed esophagostomy, at the site of a postsurgical or...
Posttraumatic wound of the esophagus that is allowed to heal by second intention as a fistula, or after penetration of the esophageal lumen (traumatic or surgical) in which leakage of saliva has caused inflammation or abscess. Pulsion diverticula are caused by fluctuations in esophageal intraluminal pressure and over-stretch damage to esophageal muscle fibers by impacted feedstuffs. A more probable cause is external trauma to the cervical area. Diverticula in the cervical esophagus should be considered when an enlargement in the neck results in dysphagia and yet a nasogastric tube can be passed. On barium swallow esophagograms, traction diverticula are spherical and have a wide neck (Fig. 31-39), whereas pulsion diverticula are flasklike in configuration, with a narrow neck. Differentiation of these two types of diverticula can be aided by additional contrast techniques that distend the esophageal lumen and outline the opening into the evagination. Esophagoscopy also defines the relative size and configuration of the opening of a diverticulum (Fig. 31-40).

A traction diverticulum, even when quite large, produces few clinical signs and seldom requires treatment. A pulsion diverticulum, however, has a tendency to enlarge progressively so that risk of obstruction and rupture increase with time. Surgical repair is indicated. A pulsion diverticulum can be repaired by diverticulectomy with resection of the mucosal-submucosal sac, followed by reconstruction of the mucosa, submucosa, and muscularis, or by inversion of the mucosal-submucosal sac with reconstruction of the muscular layer. Diverticulectomy should be used when the mucosal sac is very large and the neck of the diverticulum very narrow. There are reports of repair of apparent congenital esophageal diverticula using this technique.

However, mucosal inversion is the preferred technique because it decreases the chance of postoperative leakage, infection, or fistula formation and does not appear to predispose to postoperative obstruction complications.

**Mucosal Inversion**

The esophagus is exposed, and the diverticulum and defect in the muscularis are identified by careful dissection (Fig. 31-41). Inadvertent perforation of the mucosa and submucosa should be repaired immediately. The edges of the muscular defect should be debrided back to healthy-appearing tissue. The sac is inverted, and the edges of the muscularis are apposed with simple-interrupted sutures of 3-0 polypropylene in a manner to avoid undue tension on the closure and prevent stenosis of the esophageal diameter.
Postoperatively, feeding should consist of soft foods for 4 to 6 weeks.

Intramural Cyst

Esophageal cysts are uncommon in all species, but several equine cases have been documented.41-43 I have seen three additional horses with esophageal cysts, a 3-year-old Morgan mare, in which the cyst lining had radiographic signs of calcification, and two yearling Quarter Horse colts, both admitted for dysphagia. In all horses, an epithelial inclusion cyst (lined by stratified squamous epithelium and filled with keratinaceous debris) was found in the esophageal wall. Mural cysts are probably a developmental anomaly.

Clinical findings include dysphagia, regurgitation, a palpable soft tissue mass in the neck, and resistance to passage of a nasogastric tube at the site of the cyst. The diagnosis can be made on survey films if the cyst has started to calcify (Fig. 31-42). However, it is better confirmed on contrast radiography by the classic appearance of a filling defect caused by a mural lesion (Fig. 31-43). Endoscopically, the esophageal lumen may appear partially occluded, but significant gross changes are usually not observed because the mucosa appears normal. Intramural esophageal cysts may be removed through enucleation with inversion or resection of redundant mucosa. The esophagus is exposed, and the cyst is identified by manipulation of a nasogastric tube within the esophageal lumen. A longitudinal incision

Figure 31-41. A, A pulsion diverticulum repaired by inversion of the mucosal/submucosal sac with reconstruction of the muscular layer. B, The edge of the muscular defect should be débrided back to healthy tissue. C, The sac is inverted, and the edges of the muscularis are apposed with simple-interrupted sutures of 3-0 polypropylene in a manner that avoids undue tension on the closure and prevents stenosis of the esophageal diameter.

![Figure 31-42](image.png)

Figure 31-42. Radiographic appearance of an inner mural inclusion cyst of the esophagus in a 3-year-old Morgan mare in which the cyst lining had radiographic signs of calcification. This is an unusual finding, as survey films are usually nondiagnostic.
is made through the muscularis over the cyst. By careful dissection, the cyst is separated from its position between the mucosa/submucosa and the muscularis and is removed intact (Fig. 31-44). The cyst can be mistaken for an abscess if it is inadvertently incised by the inexperienced surgeon. Positioning the nasogastric tube caudal to the cyst helps prevent inadvertent perforation of the mucosa. After the cyst is removed, it leaves an area of redundant mucosa, or a sac, which may be treated as a pulsion diverticulum (i.e., by inversion, preferably, or by diverticulectomy). The muscularis is closed with simple-interrupted 3-0 sutures of polydioxanone or polypropylene at the surgeon’s preference.

**Megaesophagus**

Megaesophagus is dilation and muscular hypertrophy of the esophagus oral (proximal) to a constricted distal segment. Although idiopathic muscular hypertrophy does occur in the horse (without dilation), it is an asymptomatic and an incidental finding at necropsy. Therefore, the term megaesophagus, as used here, includes congenital ectasia (dilation of unknown origin), achalasia (failure of the distal esophagus to relax because of neural dysfunction, resulting in proximal dilation), and megaesophagus secondary to vascular ring anomalies. One case of vascular ring anomaly causing megaesophagus in a foal has been reported. The anomalous defect was a result of a persistent right aortic arch and was suspected on radiographic examination and confirmed on necropsy. Another case of megaesophagus was reported secondary to chronic gastroesophageal reflux.

Although hypomotility of the esophagus has been documented in one foal and neural defects of the esophagus were found in another, achalasia as defined in dogs and humans has not been reported. Treatment of these horses was not successful, even with a modified Heller’s myotomy in one foal. I have treated congenital ectasia con-
servatively with good results. A 5-month-old foal was admitted because of recurrent choke that began at the time of weaning. Esophageal lavage produced 8 L of feed regurgitated through the nasogastric tube. On radiography and endoscopy, generalized ectasia was found from the mid-cervical to the mid-thoracic esophagus (Fig. 31-45), with an annular ring noted at the point where the esophagus passed through the thoracic inlet (Fig. 31-46). The foal was fed a mash diet (pellets mixed with warm water) for 6 months, with the feed trough elevated above the animal’s withers. The mash diet was changed to complete pelleted feed for an additional 6 months before the horse was fed normal feed. Although fluid did not pool in the lumen of the esophagus after 6 months of the mash diet and the size of the dilated esophagus did not change over the next 24 months during several radiographic examinations, the horse could eat normally and is being used for show and pleasure riding. Conservative management of this problem should be considered if the owners are willing to provide the extensive nursing care (no access to roughage, including bedding in the stall, and total confinement, with exercise in-hand only) and are willing to face the possibility of several episodes of “choke” requiring treatment.

Reduplication

It is not clear whether reduplication of the esophagus is a congenital or an acquired condition, but it is included here for the sake of completeness. This condition has been reported twice. Clinical signs were similar to those of other forms of esophageal obstruction. Diagnosis may be difficult, but the problem does appear to be amenable to surgery. This condition closely resembles one of the complications of esophagostomy tube feeding, in which a dissecting tract develops parallel to the esophageal wall or within it, causing signs of obstruction.

Neoplasia

Neoplasms causing signs of esophageal obstruction are rare. Squamous cell carcinoma is the most common neoplasm and has been reported in detail in four cases. One was an extension of gastric carcinoma, one was located in the tracheal bifurcation, and two were located in the distal cervical esophagus. Biopsy and cytologic examination of brush samples obtained through the endoscope may provide an early diagnosis before stenosis of the esophagus develops, but advanced cases may be detected on radiography. The value of resection is questionable.

COMPLICATIONS OF ESOPHAGEAL SURGERY

The surgeon has the following three clinical objectives: (1) to obtain leak-proof healing of a primary anastomosis or incision, (2) to dilate a restricted aperture, and (3) to return the enlarged or disrupted esophagus to near-normal size and function. Despite meticulous technique, complications can occur. If managed properly, however, they can be resolved with a favorable outcome for the patient.

Dehiscence and Stricture

The keys to handling breakdown of a sutured esophageal incision are early recognition and treatment. For this reason, a suction drain placed next to the esophagus at the time of surgery serves a second function in addition to drainage of the serum and blood from the surgical site. It provides a method to detect salivary leakage. Not all incisions that leak saliva dehisce, especially if the saliva is removed from peri-esophageal tissues. However, if extreme amounts of saliva are leaking through the incision or complete dehiscence occurs, the original approach incision should be completely opened and lavaged daily to remove any ingesta or saliva. Dissection planes ventrally along the trachea should be drained to the outside to prevent eventual mediastinitis or pleuritis. Dissecting infections can occur after esophagostomy as well, and inadvertent placement of a dislodged feeding tube into a dissection plane or the thorax would clearly have an unfavorable outcome.

The patient may be permitted to drink, which in many cases lavages the wound. Nutritional requirements may be met by oral feeding or placement of a feeding tube into the esophagus at the point of dehiscence or distally through a

Figure 31-45. Positive-contrast esophagogram shows megaeosophagus at the mid-cervical level. The foal was managed with a mash diet and recovered esophageal function over a 1-year period.

Figure 31-46. Barium pressure esophagogram shows megaeosophagus in the foal seen in Figure 31-45. Note the narrowing of the esophageal lumen as it passes through the thoracic inlet.
separate esophagostomy. The outcome of this complication from this point depends on management of water and electrolyte balance. The most common complication after treatment of an annular lesion is stricture (see Fig. 31-30). This complication is the bane of the esophageal surgeon, and its successful treatment is limited by the owner’s financial commitment.

**Acid–Base and Electrolyte Alterations**

In the face of adequate nutrition, daily losses of large amounts of saliva result in hyponatremia, hypochloremia (Fig. 31-47), and transient metabolic acidosis followed by progressive metabolic alkalosis (Fig. 31-48). The alkalosis probably results from renal compensation for electrolyte imbalances. Oral administration of sodium chloride daily reverses the electrolyte imbalance (potassium requirements are adequately met in feed); alkalosis is corrected through renal mechanisms.

**Laryngeal Hemiplegia**

Manipulative procedures or disease of the esophagus in the cervical area can easily result in laryngeal hemiplegia because of the proximity of the recurrent laryngeal and vagus nerves. The surgeon should be aware that apparently minor manipulations of these nerves can have deleterious effects on their function.

**Carotid Artery Rupture**

Chronic feeding tubes placed in the distal third of the cervical esophagus can lead to jugular vein or carotid artery ulceration. Bleeding episodes should be an indication for exploratory and vessel ligation to prevent exsanguination.

CHAPTER 32

Stomach and Spleen
Anthony T. Blikslager
David A. Wilson

STOMACH
Anatomy

The equine stomach is small relative to the body size of the horse, having a capacity of approximately 5 to 15 L.1 Even when the stomach is filled to capacity, it does not reach the ventral body wall. It is located predominantly on the left side of the abdomen under the cover of the ribs, with only the pyloric aspect of the stomach to the right side of midline. Its most caudal component is the fundus, which lies adjacent to the 14th and 15th rib spaces (Fig. 32-1).2 The stomach can be divided into several regions, including the cardia at the opening of the esophagus, the fundus (which forms a blind sac), the body, and the pyloric region. The stomach is sharply curved at its lesser curvature so that the cardia and pyloric regions lie adjacent to one another.3 The cardia is attached to the diaphragm by the gastrophrenic ligament. This ligament is a continuation of the phrenicosplenic ligament and the gastrosplenic ligament on the left side of the abdomen. The greater omentum attaches along the greater curvature of the stomach to the right side of midline. The proper gastric mucosa contains enterochromaffin-like (ECL) cells that secrete histamine in response to various stimuli, which in turn amplifies HCl secretion by the parietal cells. The pyloric mucosa contains both G-cells, which secrete gastrin, and D-cells, which secrete somatostatin. These hormones enhance or reduce gastric acid secretion, respectively.4

Physiology

During digestion, the stomach is capable of dramatically lowering the pH of its contents, and of secreting pepsinogen to begin breaking down protein. However, both HCl and pepsinogen (which is converted to pepsin) are inherently damaging to mucosa, which possesses a number of mechanisms to prevent injury, depending on the region of the stomach. There are four regions of the stomach based on the type of mucosal lining (in an orad-to-aborad order): nonglandular stratified squamous epithelium, cardiac epithelium, proper gastric mucosa (glandular mucosa), and pyloric mucosa.3 The equine stomach has a very extensive region of stratified squamous mucosa that occupies approximately half of the stomach mucosal surface area, and this changes abruptly to cardiac glandular mucosa at a line of demarcation called the margo plicatus.4 The function of the stratified squamous mucosa in the horse is unknown, since this region of the stomach does not have the ability to secrete ions, although the squamous mucosa may protect underlying tissues from abrasion by roughage.5 However, the squamous mucosa does not frequently come into contact with stomach contents, as the gastric fill line is typically the margo plicatus. The cardiac epithelium forms a belt of tissue adjacent to the margo plicatus. Relatively little is known about this mucosal region, although it has the ability to secrete bicarbonate in other species and has been shown to contain cells capable of secreting somatostatin in equine mucosa, which serve as a negative feedback mechanism for gastric acid secretion. The proper gastric mucosa contains secretory glands containing HCl-secreting parietal cells and pepsinogen-secreting zymogen cells. In addition, this segment of mucosa contains enterochromaffin-like (ECL) cells that secrete histamine in response to various stimuli, which in turn amplifies HCl secretion by the parietal cells. The pyloric mucosa contains both G-cells, which secrete gastrin, and D-cells, which secrete somatostatin. These hormones enhance or reduce gastric acid secretion, respectively.4

Gastric Barrier Function

Mechanisms by which the stratified squamous mucosa resists injury are critical in the horse, where ulceration is prevalent.5-7 When mounted in Ussing chambers for the purpose of measuring epithelial transport function, equine stratified squamous epithelium has baseline transepithelial resistance measurements of approximately 2000 to 3000 ohms.cm², which is an order of magnitude higher than that of the adjacent cardiac mucosa.8 Since transepithelial resistance is essentially a measure of permeability to ions, the stratified squamous mucosa is exceptionally impermeable. This is the only mechanism of defense against injury present in this type of mucosa. The stratified squamous epithelium consists of four layers: the outer stratum corneum, the stratum transitionale, the stratum spinosum, and the basal stratum germinativum. However, not all of these layers contribute equally to barrier function. Interepithelial tight junctions in the stratum corneum, and muco-substances secreted by the stratum spinosum are mainly responsible for barrier function.9,10 The stratified squamous mucosa in other species is relatively impermeable to HCl,10 suggesting that although...
most of the literature on equine ulceration pertains to the effects of HCl and inhibitors of HCl secretion, although other factors may be critical to the development of gastric ulcer disease. Nonetheless, exposure of equine stratified mucosa to acid (pH 1.7) results in significant reductions in measurements of transepithelial electrical resistance, regardless of whether other injurious compounds are added, indicating that acid alone can damage the mucosa. What is not clear is whether less acidic solutions can also cause damage alone, or whether other injurious factors, such as bile or pepsin, become important.

The site of HCl secretion (proper gastric mucosa) is protected from so-called back-diffusion of H+ ions by a relatively high transepithelial electrical resistance (compared to cardiac mucosa), but there is also a number of other critical mechanisms to prevent acid injury. The gastric mucosa secretes both mucus and bicarbonate, which together form an HCO3–-containing gel that titrates acid before it reaches the lumen. However, the mucus layer does not form an absolute barrier to back-diffusion of acid. Thus, for acid that does diffuse back into the gastric mucosa, epithelial Na+/H+ exchangers are capable of expelling H+ once the cell reaches a critical pH.

**Gastric Mucosal Pathophysiology**

**Mechanisms of Gastric Ulceration**

Ulceration in horses most commonly involves the stratified squamous epithelium and is somewhat analogous to gastroesophageal reflux disease in people. This may occur because the glandular portion of the stomach has a number of protective mechanisms, including mucus and bicarbonate secretion, whereas the squamous mucosa has none of these protective mechanisms and is periodically exposed to acid contents. Although stratified squamous epithelium is relatively impermeable to HCl, a number of factors can dramatically enhance the damaging effects of HCl in this epithelium. In particular, bile salts and short-chain fatty acids are capable of breaking down the squamous epithelial barrier at an acid pH, thereby exposing deep layers to HCl, with subsequent development of ulceration. Relatively high concentrations of short-chain fatty acids normally exist in the equine stomach as a result of microbial fermentation. These weak acids penetrate squamous mucosa, and they appear to damage Na+ transport activity, principally in the stratum germinativum. Bile salts may also be present in the proximal equine stomach as a result of reflux from the duodenum. Although such reflux has a relatively high pH, it appears that bile salts adhere to stratified squamous epithelium, becoming lipid soluble and triggering damage once the pH falls below 4. Diet and management (e.g., periods of fasting) also play crucial roles in the development of conditions conducive to gastric ulceration. Typically, there is a pH gradation in horses from proximal to distal compartments of the stomach, with the lowest pH values in the distal stomach. However, during periods of fasting, this stratification is disrupted, so that low pH values may be recorded in the proximal stomach. Fasting conditions also increase the concentration of duodenal contents within the proximal stomach, particularly bile. The type of diet also influences the stratification of stomach contents.

Mechanisms inducing injury to proper gastric mucosa may be entirely different from those inducing injury to stratified squamous mucosa. In people, the majority of gastric mucosal ulcers are induced by infection with *Helicobacter pylori*, which has the effect of raising gastric pH because of disruption of gastric glands, but which also induces an inflammatory reaction that causes damage. In particular, *H. pylori* containing the *cagA* gene is most pathogenic. However, there is very little evidence that this organism is involved in gastric ulcers in domestic animal species. In the absence of a known role for infectious agents in equine gastric ulcer disease syndrome, ulceration most likely develops from an imbalance between protective mechanisms and injurious factors, which include gastric acid, bile, and nonsteroidal anti-inflammatory drugs (NSAIDs). However, some factors that are important to induction of squamous epithelial ulceration may not be important in development of proper gastric mucosal ulceration. For example, feed deprivation and intensive training reproducibly induce squamous epithelial ulceration in horses, but they have little effect on proper gastric mucosa in horses. Gastric acid very likely plays a key role, whereas other factors such as NSAIDs serve to reduce gastric defense mechanisms. In particular, inhibition of prostaglandin production reduces mucus and bicarbonate secretion, while also reducing gastric mucosal blood flow, and would be expected to produce ulceration of proper gastric mucosa. In addition, some of the NSAIDs also have a topical irritant effect, but this appears to be of minor significance, since the route of administration (oral or parenteral) seems to have little influence on development of ulceration.

**Gastric Reparative Mechanisms**

Mechanisms of gastric repair are highly dependent on the extent of injury. For instance, superficial erosions can be rapidly covered by migration of epithelium adjacent to the wound—a process termed epithelial restitution. However, ulceration (full-thickness disruption of mucosa and penetration of the muscularis mucosae) requires repair of submucosal vasculature and matrix. This is initiated by formation of granulation tissue, which supplies connective tissue elements and microvasculature necessary for mucosal reconstruction. Connective tissue elements include proliferating fibroblasts that accompany newly produced capillaries that form from proliferating endothelium. Recent studies indicate that nitric oxide is critical to both of these processes, which probably explains the reparative properties of NO in the stomach. Once an adequate granulation bed has been formed, newly proliferated epithelium at the edge of the wound begins to migrate across the wound. In addition, gastric glands at the base of the ulcer begin to bud and migrate across the granulation bed in a tubular fashion. Epidermal growth factor is expressed by repair epithelium, and it appears to facilitate these processes. In addition, these events are facilitated by a mucoid cap, which retains reparative factors and serum adjacent to the wound bed. Importantly, this cap maintains a neutral pH to facilitate healing. Once the ulcer crater has been filled with granulation tissue and the wound has been reepithelialized, the subepithelial tissue remolds by altering the type and amount of collagen.
Diagnostic Techniques

Endoscopy
Prior to gastric endoscopy, foals up to 20 days of age should be held off feed for 3 hours, whereas older foals require up to 10 hours to sufficiently empty the stomach. Adult horses should be held off feed for 24 hours to allow complete visualization of the stomach. A 3-m endoscope is required to adequately visualize the stomach, including the pylorus, in adult horses, whereas a 1-m endoscope may be sufficient for foals. Although endoscopy is the principal diagnostic aid for detection of gastric ulceration, a recent study comparing endoscopic to histologic scoring of the severity of ulceration indicated that endoscopy tends to underestimate the number and severity of gastric ulcers of the nonglandular equine stomach. Furthermore, endoscopy may not allow detection of glandular gastric ulcers. Therefore, clinicians should realize that ulceration is frequently more severe and extensive than that observed via the endoscope.

Ultrasonography
Ultrasoundography can be used to image the wall of the stomach, and it may be particularly useful in foals with suspected gastric outflow obstruction. The stomach is best imaged from the left side of the abdomen between rib spaces 8 and 14. If gastric outflow obstruction is present, a distended stomach with a gas-fluid interface may be detected. The duodenum can also be imaged at this site, and it may show evidence of thickening and reduced motility. The duodenum can additionally be imaged from the right paralumbar fossa, cranial to the right kidney, where there may be additional evidence of thickening or obstruction.

Radiography
Contrast radiography can be performed to allow visualization of the stomach. In a series of foals with gastroduodenal obstruction, barium sulfate solution was administered. In addition, functional gastric emptying can be determined by the administration of barium sulfate after a 12- to 18-hour fasting period. In normal horses, barium appears in the small intestine by 10 minutes, and none remains within the stomach by 35 minutes. With pyloric outflow obstruction, barium may remain in the stomach for up to 8 hours. Barium sulfate solutions should be diluted 1:1 with water, and a volume of approximately 1 L should be administered into the thoracic portion of the esophagus by nasogastric tube. Double-contrast radiography with insufflation of air, followed by administration of a barium sulfate suspension, can enhance visualization of the stomach. This technique has been useful in the diagnosis of gastric outflow obstruction and gastric neoplasia.

Measurement of Gastric Emptying
Assessment of gastric emptying can be performed by nuclear scintigraphy, acetaminophen absorption, or breath testing after the administration of 13C-octanoic acid. For scintigraphic determination of gastric emptying, one study involved administration of 370 megabecquerels of 99m-technetium sulfur colloid incorporated into egg albumin (to determine solid phase gastric emptying) and 37 MBq of 111-indium-labeled diethylenetriamine-penta-acetic acid (DTPA) in 120 mL of water (to determine liquid phase gastric emptying). These labeled products were administered via a nasogastric tube after a 12-hour fasting period. Scintigraphic images obtained from the left and right flanks were then used to assess gastric emptying. Liquid phase and solid phase 50% gastric emptying times are 30 and 90 minutes, respectively, in normal horses. In experimental trials assessing efficacy of breath testing, ponies were fasted for 14 hours, after which they ingested a test meal with 13C-octanoic acid. Breath samples were then analyzed by mass spectrometry for the appearance of the isotope. This method correlated closely with gastric emptying documented with nuclear scintigraphy after administration of Tc99m sulfur colloid. Similarly, acetaminophen absorption has been shown to closely correlate with scintigraphic measurements of gastric emptying. For example, in one research trial, acetaminophen (20 mg/kg) and Tc99m pertechnetate (10 mCi) were administered in 200 mL water, and their clearance from the stomach was shown to be similar, based on serum acetaminophen and scintigraphic analyses, respectively.

Disorders

Gastric Ulcer Clinical Syndromes
The clinical syndromes of gastric ulceration are age dependent; the age categories are neonates, weanling foals, and horses older than 1 year. In neonates, ulceration of the glandular mucosa is the most clinically important. Clinical signs include poor appetite, colic, and diarrhea, but foals may have ulcers and not demonstrate overt clinical signs of gastric pain or failure to thrive. The pH of neonatal gastric contents is not typically as low as that of older foals or adults, suggesting that other factors may be important in the pathogenesis of ulceration.

In suckling and weanling foals, ulceration frequently occurs in the squamous mucosa adjacent to the margo plicatus. Severe ulceration of the squamous portion of the stomach in foals of this age group is frequently associated with diarrhea, but foals may also appear unthrifty, with a rough hair coat and a pot-bellied appearance. Diffuse ulceration is also typically associated with teeth grinding and colic. This age group of foals may also be affected with gastroduodenal ulceration, which may result in gastric outflow obstruction (see later).

In yearlings and adult horses, lesions also occur predominantly in the squamous portion of the stomach adjacent to the margo plicatus. These horses may have very subtle signs of disease, such as poor performance, reduced appetite, and failure to thrive, but they do not typically suffer from diarrhea. The diagnosis of gastric ulcers is confirmed with gastroscopy. When evaluating squamous lesions in foals, it is important to differentiate ulceration from desquamation. The latter involves shedding of sheets of epithelium without ulceration, and it is unlikely to be clinically important. Treatment is aimed at elevating the pH of the gastric contents, which may be achieved with a number of histamine receptor (H2) antagonists, such as ranitidine (6.6 mg/kg, PO every 8 hours, or 1.5 to 2 mg/kg IV every 6 to 8 hours) or proton pump inhibitors such as omeprazole (2 to 4 mg/kg PO every 8 hours).
**Gastric Impaction**

Impaction of the stomach typically consists of excessive dry, fibrous ingesta, but it may also consist of ingested materials that form a mass, such as persimmon seeds or mesquite beans. Other feeds that tend to swell after ingestion, including wheat, barley, and sugar beet pulp, may also cause impaction. Furthermore, dental disease may increase the likelihood of gastric impaction because of improper chewing of feed. Clinical signs include colic that ranges from acute to severe to chronic and mild. For example, in one report on four horses with gastric impaction, colic was moderate or severe and of 8 to 12 hours’ duration, whereas in another report on a pony with gastric impaction, colic was chronic (7 days’ duration) and associated with prolonged recumbency, anorexia, and lethargy. Additional signs may include dysphagia, dropping of feed, and bruxism.

The diagnosis is frequently made at the time of surgery, although endoscopy reveals gastric impaction and may provide information on the specific nature of the impaction. Medical treatment includes nasogastric intubation and frequent attempts at softening the ingesta with water, followed by refluxing the fluid contents, or by using back-and-forth agitating movements of water with a 16-ounce dose syringe attached to the nasogastric tube. At surgery, the impaction can be massaged and infused, most commonly via insertion of a needle adjacent to the greater curvature, followed by infusion of a balanced polyionic fluid such as saline. There is also a report including the details of a pony and a horse in which the impacted stomach was packed off from the abdomen with towels, and an incision was made parallel and caudal to the attachment of the omentum on the greater curvature of the stomach. The stomach contents were then evacuated, followed by a double-layer inverting closure. In the horse in this report, the ventral midline incision was extended cranially to the xiphoid process. However, this aggressive approach is seldom necessary, as the impaction can usually be resolved with more conservative management.

**Gastric Rupture**

Rupture of the stomach appears to have two general causes: primary, where there may be excessive accumulation of ingesta, or no identifiable cause, and secondary, in which another causative condition, such as obstruction of the small intestine, is identified. The site of the rupture is most commonly the greater curvature of the stomach, although other sites of rupture have been identified, including the lesser curvature of the stomach. The condition is almost universally fatal, because the rupture of stomach contents into the abdomen causes septic shock that cannot be adequately reversed with abdominal lavage and repair of the stomach defect. However, there are some case reports of gastric rupture that has been repaired. In one report, subserosal hematoma associated with a focal serosal perforation was repaired by use of a two-layer inverting closure, and the horse survived. In another report, a seromuscular tear with intact mucosa bulging from the tear was noted, and it was oversewn with an inverting suture pattern. However, in neither case was there any evidence of abdominal contamination with gastric contents.

In a report on 54 horses, 11% of deaths in horses with colic taken to surgery were attributable to gastric rupture. Interestingly, at least 6 of the 54 horses had indwelling stomach tubes, indicating that nasogastric intubation does not negate the possibility of gastric rupture. In a separate report on gastric rupture, it was determined that 5.4% of all colic accesses had gastric rupture. One of the most striking clinical findings was that the abdominal fluid cell counts were frequently inaccurate, most likely because the acid stomach contents lysed cells infiltrating into the abdomen. However, a number of abdominal fluid samples were not analyzed because they had the appearance of ingesta. This report also determined a number of risk factors for gastric rupture, including the feeding of a diet exclusively of grass hay, or grass and alfalfa hay, and drinking water from a bucket, stream, or pond. Alternatively, horses fed grain had a reduced risk. The cases in this study were principally primary gastric ruptures (60%), and predisposing factors may include the opportunity to consume excessive water or roughage, which may then expand and rupture the stomach.

**Gastric Neoplasia**

Neoplasia of the stomach is rare. The most common form of gastric neoplasia is squamous cell carcinoma, which typically forms in the cardia of the stomach. In one report, a tumor encircled the esophagus at the cardia of the stomach, where it caused recurrent esophageal obstruction. Clinical signs may include anorexia, weight loss, abdominal distention, abnormal chewing behavior, dysphagia, fever, and ventral abdominal edema. The diagnosis can be based antemortem on results of gastric endoscopy and biopsy, or on thoracoscopy and biopsy. In addition, approximately 50% of horses have had neoplastic cells evident in abdominal fluid or in thoracic fluid. Other nonspecific laboratory findings have included anemia, neutrophilia, and hypalbuminemia. Additionally, one horse had a clinical diagnosis of pseudohyperparathyroidism in association with gastric carcinoma, based partially on evidence of hypercalcemia and hypophosphatemia. In a case series on gastric squamous carcinoma, horses have had multiple metastases, including masses throughout the abdomen. Therefore, the prognosis is grave, and the condition has been universally fatal.

Other neoplasms that have been identified in the stomach include leiomyosarcoma and adenocarcinoma. A leiomyosarcoma was diagnosed in a 12-year-old Thoroughbred gelding that was evaluated because of anorexia, weight loss, and intermittent fever. At surgery, an inoperable mass was discovered in the cranial abdomen, which was found to be a leiomyosarcoma after histopathologic analysis. The mass was associated with the distal portion of the esophagus and the cranial two thirds of the stomach. Adenocarcinoma has been documented in the glandular portion of the equine stomach.

**Gastric Outflow Obstruction**

Gastric outflow obstruction may be the result of pyloric stenosis, which can be caused by congenital muscular hypertrophy, or by development of a mass at the pylorus that reduces gastric outflow. A mass may develop at the pylorus associated with gastroduodenal ulceration or neoplasia. Clinical signs include weight loss, reduced appetite,
abdominal pain, teeth grinding, and ptyalism. Foals with gastric outflow obstruction are typically 2 to 6 months of age, with signs of gastric ulceration and an unthrifty appearance. However, foals may also have a history of enteritis, and an absence of clinical signs typical of foals with gastric ulcers.31

Gastric outflow obstruction can be diagnosed using endoscopy, radiography, ultrasonography, and gastric emptying tests, as described previously. Medical treatment for foals includes decompression of the stomach, antiulcer medications, broad-spectrum antibiotics, prokinetics, and intravenous fluids. However, surgery is indicated if medical treatment does not reverse clinical signs within a short period of time.31 The principle of surgery for treatment of gastric outflow obstruction is bypass of the pylorus, typically by performing a gastrojejunostomy. Pyloric stenosis has been relieved in a 2-month-old Thoroughbred by a modification of the Heineke-Mikulicz technique, in which a full-thickness longitudinal incision through the pylorus was closed transversely.61 The pylorus was mobilized by severing the hepatoduodenal ligament.

Alternatively, a series of bypass techniques can be performed, depending on the location of the obstruction.33 In one series evaluating surgical results in 13 foals with gastroduodenal obstruction, bypass procedures included gastroduodenostomy, duodenojejunostomy, or gastrojejunostomy. A jejunojejunostomy was also performed with the latter two surgical procedures to allow outflow of proximal small intestinal contents.32 These anastomoses can be hand-sewn or performed with automated stapling equipment (Figs. 32-2 to 32-4). However, hand-sewn anastomoses may be simpler to perform because of the limited space within a foal’s abdomen, which reduces maneuverability of larger stapling instruments.13 Although a three-layer hand-sewn technique has been described (seromuscular, muscular, and mucosal layers), one case report suggested that a two-layer hand-sewn anastomosis (seromuscular and mucosal layers) was sufficient and more rapidly performed in a foal in which a gastroduodenostomy was created.33

The prognosis for foals with gastric outflow obstruction is guarded.31 In one report on results of surgical intervention in foals with gastroduodenal obstruction, 6 of 13 foals (46%) survived.52 One report indicated that foals with a localized pyloric obstruction should have a more favorable prognosis than foals with pyloric and duodenal obstructions, because the surgery for the former (gastroduodenostomy) is simpler than the surgery for the latter (gastrojejunostomy and jejunojejunostomy).33

**Spleen**

**Anatomy**

The spleen is a falciform or sickle-shaped organ located in the left mid-dorsal part of the peritoneal cavity (Fig. 32-5). The exact position of the spleen varies, depending on, for example, the amount of the stomach filling, intestinal distention or displacement, and splenic disease. The cranial border of the spleen is concave and the caudal border is convex. The parietal or lateral surface is slightly convex and is in intimate contact with the diaphragm.65 The visceral or
medial surface is generally concave and contains a longitudinal ridge, the hilus, in which the vessels and nerves are located. The area cranial to the hilus is in contact with the left side of the greater curvature of the stomach. The area caudal to the ridge is more extensive and is variably in contact with the descending colon, and the left parts of the ascending colon and the small intestine. The dorsal extremity or base of the spleen is located between the left crus of the diaphragm and sublumbar muscles dorsally, and on its medial surface by the pancreas and left kidney. The base generally corresponds to the last three or four ribs, exceeding the 18th rib caudally in the paralumbar fossa by 2 to 3 cm. Only the caudodorsal angle (between the base and the caudal border) can be palpated per rectum. The ventral extremity or apex is small and usually found opposite the 9th, 10th, or 11th rib, proximal to the costal arch. The spleen is suspended within the peritoneal cavity by means of the phrenicosplenic and the renosplenic (or nephrosplenic) ligaments, and attached to the stomach by the gastrosplenic ligament. The latter continues with the superficial wall of the greater omentum.

The size and weight of the spleen vary greatly, both among and within animals, depending on the amount of blood it contains. Its weight varies from about 0.5 to 3.5 kg. The spleen is approximately 50 cm long and about 20 to 25 cm wide. It is usually bluish red to purple.

The hilus protects the vessels and nerves of the spleen. The splenic artery, a branch of the celiac artery, runs within the groove of the hilus and branches to supply the spleen and short gastric arteries that nourish the greater curvature of the stomach (Fig. 32-6). The splenic vein is an affluent of the portal vein and lies caudal to the artery in the hilus. The splenic lymph nodes are scattered along the splenic artery and drain lymph to the celiac lymphocenter. The splenic plexus, branching from the celiac plexus, supplies the spleen with both sympathetic fibers from the major splanchnic nerve and parasympathetic fibers from the vagus nerve.

The splenic tissue is intimately covered by a fibrous capsule, which sends numerous trabeculae into the substance of the spleen. The capsule consists of collagen and elastin fibers and contains many smooth muscle cells. The trabeculae form a spongy framework, which is the support of the splenic pulp. The splenic pulp is mostly red or dark red and is known as the red pulp. The red pulp consists of arterial capillaries, small venules, and a reticulum filled with macrophages and blood. Throughout the red pulp are scattered gray foci just visible to the naked eye, which are known as the white pulp. The white pulp represents the lymphatic tissue of the spleen organized as lymphatic nodules. Lymphocytes and macrophages supported by a scaffolding of branched connective cells called reticular cells make up the lymphatic tissue. The reticulum is made up of a meshwork of supporting cells and extracellular fibers. The white pulp is distributed along the course of the arterial vessels, and it is almost as abundant as the red pulp.

### Physiology

The spleen has several important functions, including storage of erythrocytes and platelets, removal of aged or damaged erythrocytes and platelets, hematopoiesis during fetal development, iron recycling, and immunologic functions.
Unlike human spleens, animal spleens have the ability to store red blood cells. The equine spleen is particularly well adapted and can regulate the red cell storage by relaxation and contraction. The equine spleen can store up to 60% of circulating red blood cells. The contractile ability is under sympathetic control and, in times of stress or strenuous exercise, is stimulated to release the stored red blood cells into the circulation, increasing the red cell concentration of the blood. At least one report has questioned the role of splenic emptying in exercise-induced changes in red cell indices.

Phenylephrine (an α1-adrenergic receptor agonist) administration has been reported to cause a transient, dose-dependent splenic contraction of up to 83% of the original splenic mass and may be useful for certain medical or surgical procedures in the horse, such as during splenectomy or as an adjunct to nonsurgical correction of nephrosplenic entrapment of the ascending colon. Epinephrine has also been reported to transiently reduce splenic length approximately 68% when administered as a bolus.

The removal of aged or damaged erythrocytes occurs in the spleen because of its unique structure. Blood is circulated through the splenic red pulp, terminating in small, highly porous capillaries. The blood cells then pass out of the capillaries into the cords of the red pulp and eventually return to circulation through the endothelial wall of the venous sinuses. The red pulp and venous sinuses are loaded with macrophages (reticuloendothelial cells), which phagocytize unwanted debris and old or abnormal red blood cells. Also removed by the phagocytic cells are abnormal platelets, bloodborne parasites, and bacteria.

In addition to its filtering and phagocytic activity, the spleen has another role in the immune-mediated defense against disease. It has a direct effect on the pattern and level of antibody response of the body. The spleen in several species has been determined to be the most important organ in the production of IgM. Decreased levels of IgM occur after splenectomy. The role of IgM occurs in the initial antibody response to disease and, therefore, splenectomized animals may be somewhat compromised.

The resistance of the horse to disease caused by blood protozoa such as *Babesia* species or *Theileria* species is significantly decreased after splenectomy. Subclinical infections by protozoa may become patent infections after removal of the spleen.

**Diagnostic Procedures**

Surgical disorders of the spleen may be relatively difficult to diagnose because of their rare occurrence and nonspecific clinical signs. Rectal palpation usually reveals thickening and rounded margins of an enlarged spleen. Ultrasonography either per rectum or through the left abdominal wall may also reveal an enlarged spleen. A splenic biopsy may be performed for histologic evaluation of splenomegaly. Normal coagulation function should be determined before a percutaneous biopsy is performed. Laparoscopy may also be used to aid in the diagnosis of splenic abnormalities and to help with the decision between medical therapy and splenectomy.

To examine the spleen, a long (30 cm) laparoscope is introduced into the dorsal aspect of the left paralumbar fossa facing cranially. The head of the spleen, left kidney, and renosplenic ligament can be readily identified in the left dorsal quadrant of the abdomen. The caudal edge and lateral wall of the spleen can be visualized as the laparoscope is swept down toward the left ventral quadrant, and abnormalities over most of the body of the spleen can be identified. Lesions in this region can be biopsied with...
additional instruments placed through separate portals in the left paralumbar fossa. Biopsies can be obtained with laparoscopic scissors as wedge biopsies, or with a biopsy instrument similar to a uterine biopsy forceps. Hemorrhage should be expected, and it can be controlled with bipolar cautery forceps. Additional diagnostic procedures used to differentiate disorders of the spleen include a complete history and physical examination, complete blood cell count, including total plasma protein and plasma fibrinogen, coagulation profile, abdominocentesis, the Coggins test (agar gel immunodiffusion test for equine infectious anemia), Coombs’ test, and aerobic and anaerobic bacterial cultures.

**Indications for Surgery**

Splenectomies are performed primarily for research purposes, to aid in the evaluation of the cardiovascular system during exercise and to alter the reticuloendothelial system, which controls to a great extent the infections caused by blood protozoa such as *Babesia* or *Theileria*. Splenomegaly with or without splenic infarction has been the only reported disease process requiring splenectomy. Other possible indications for surgery include neoplasia, trauma, rupture, infarction, and possibly an autoimmune disease in which the spleen would play a role in erythrocyte destruction.

**Splenomegaly**

Splenomegaly in the horse has been attributed to subcapsular hematoma, equine infectious anemia, lymphoma, metastatic melanoma, iso-immune hemolytic anemia, salmonellosis, anthrax, and chronic congestion. Infarctions have also been reported as causes or consequences of splenomegaly. Splenectomy is indicated for splenomegaly for chronic congestion, thrombosis, or primary tumors of the spleen with no evidence of metastases. Clinical signs of horses with splenomegaly include tachycardia, anemia, colic, arching of the back, and standing with the limbs drawn together beneath the body.

**Neoplasia**

Lymphosarcoma (malignant lymphoma), metastatic melanoma, and hemangiosarcoma are the only primary neoplastic diseases of the equine spleen. Lymphosarcoma is a neoplastic disease of cells of the lymphoid cell series. Splenic lymphosarcoma is classified as an alimentary form of the disease. The cells metastasize via the lymphatics (i.e., in the spleen, the white pulp is first infiltrated). In later stages of the disease, the spleen’s architecture may become so distorted that the pathway of spread is not apparent. Leukopenia and anemia are often present.

Melanomas may occur as a primary tumor of the spleen of horses, but the spleen is more likely a site of metastasis. Hemangiosarcoma or hemangiendothelioma is a frequent primary tumor of other domestic animals and humans but has been only rarely reported as a primary tumor in the horse. This tumor is more commonly reported in the spleen of the horse as a site of metastasis. All of these tumors may cause splenomegaly and may present with clinical signs of an acute abdominal disease because of an increased weight of the spleen and stretching of the splenic ligaments.

**Splenic Infarction and Splenic Abscesses**

Splenic infarction occurs concurrently with splenomegaly. Venous thrombosis and infarction may occur any time the spleen is enlarged. Splenic arterial or venous thrombosis, or both, is seen with autoimmune hemolytic anemia, purpura, hemorrhagic pancreatitis, and splenic abscess. Splenic abscesses have been reported to be caused by *Habronema*, *Strongylus*, *Bacteroides*, *Clostridium*, and *Streptococcus*.

**Splenic Rupture**

Splenic rupture is relatively uncommon in horses. It may be caused by direct, severe trauma, or it may occur secondary to anthrax, lymphosarcoma, echinococcus infestation, or splenic hematoma or hemorrhage. In all reported cases, horses have been found dead, died during the course of the illness, or were euthanatized shortly thereafter. The cause of rupture is usually unknown, but in one report, it was thought to be as a result of a previous splenomegaly. Most of the ruptures occur on the visceral surface of the spleen. Very few cases of rupture to the parietal surface have been reported. Two cases of nonfatal subcapsular hematoma on the parietal surface have been reported. The clinical signs include serosanguineous or sanguineous peritoneal fluid, pale mucous membranes, anemia, tachycardia, dyspnea, profuse sweating, anorexia, and colic. Immediate surgery is indicated to control hemorrhage.

**Preoperative Considerations**

Preoperative considerations for splenectomy include assessment of hydration, acid–base status, and clotting function. The presentation of horses requiring a splenectomy is usually on an emergency basis (i.e., acute abdominal disease, acute blood loss), and therefore the horses may be dehydrated and in shock. Careful assessment should differentiate those with pain because of stretching of the splenic ligaments from those with pain because of acute blood loss from splenic rupture.

**Surgical Techniques**

**Splenectomy**

**APPROACHES**

Several reports have described the technique for splenectomy. All the methods describe an approach from the left side, with the animal standing or in right lateral recumbency. The variations in the techniques center on the exact position of the skin incision. Originally, the procedure was described as a paralumbar approach (i.e., caudal to the last or 18th rib). Because of the difficulty in accessing the base of the spleen, and therefore its primary vessels, various techniques have been proposed to gain better access. Techniques have been described for access to the spleen between the last two ribs, resection of the 18th rib, and...
the 17th rib, or the 16th rib. One report also describes removal of the distal aspect of the last three ribs. Another report describes removal of the 17th and transecting of the 16th and 18th ribs for removal of an enlarged spleen.

Laparoscopic splenectomy has been reported in humans, but its potential use in the horse at this time is only speculative. Hand-assisted techniques may soon be developed similar to those reported for removal of diseased kidneys and ovarian tumors in horses. The friability of the diseased spleen and its vascular supply will very likely complicate potential laparoscopic procedures, although the visualization afforded by laparoscopy may well offset the potential complications.

The caudal reflection of the pleural cavity should be considered when determining the technique to be used. The lateral thoracic wall attaches to the diaphragm along a line called the diaphragmatic line of pleural reflection. This line extends from the eighth and ninth costal cartilages dorsocaudally in a gentle, increasing curve, so that its most caudal aspect is at about the middle of the cranial border of the last rib forming the caudal border of the pleural cavity. Therefore, resection of either the 16th or 17th rib is almost always associated with opening the pleural cavity, resulting in a pneumothorax. This is not necessarily a significant problem, because many horses have an intact mediastinum. However, if the mediastinum is incomplete, assisted ventilation is required to maintain respiration.

17TH RIB RESECTION TECHNIQUE

The horse is placed under general anesthesia in right lateral recumbency and prepared for aseptic surgery. A vertical incision is made over the 17th rib from the lumbar muscles (iliocostalis thoracis and longissimus muscles) proximally to the costochondral junction distally. The dissection continues through the subcutaneous tissues, and the cutaneous trunci, serratus dorsalis caudalis, and external abdominal oblique muscles to expose the lateral periosteum of the 17th rib. The periosteum is incised and elevated from the lateral aspect of the rib with a periosteal elevator starting at the costochondral junction and continuing proximally. Circumferential elevation of the periosteum over the full length of the exposed rib is achieved using a large Doyen, Alexander, or other similar periosteal elevator. An obstetrical cable (Gigli wire), bone-cutting forceps, or an oscillating bone saw is used to transect the rib as far proximally as possible. The body of the rib is disarticulated at the costochondral junction through lateral and ventral pull and is removed. The medial periosteum and underlying peritoneum are incised. Proximally, the pleural cavity may be entered. The cavity should be closed by suturing the diaphragm to the intercostal muscles using an absorbable suture in a continuous pattern. While the pleural cavity is open, the horse’s respiration may need to be assisted with mechanical ventilation or intermittent manual compression of the rebreathing bag.

The edges of the incision should be draped with saline-moistened laparotomy sponges and separated with a Finochietto rib spreader. The dorsal part of the spleen may be elevated into the incision (Fig. 32-7). The nephrosplenic ligament is transected to expose the splenic vein. The vein is located more superficial or lateral than the artery and may be isolated for separate ligation. Care should be taken not to tear the vein. Intravenous infusion of phenylephrine will result in significant, transient splenic contraction to reduce the weight of the spleen and allow better access to its visceral portion. Some specialists recommend separate ligation of the vessels, with the artery being ligated first and the spleen massaged to remove any excess blood from the organ. A variation is to inject 10 to 15 mL of 1:1000 epinephrine at several sites in the spleen to expedite its contraction. The vessels should be triple-ligated and transected between the distal ligatures, leaving two ligatures on each (if ligated separately) of the vessels. The remainders of the nephrosplenic, phrenicosplenic, and gastrosplenic ligaments are transected near the hilus. Ligatures or stainless steel hemo-
static clips are applied to the short gastric vessels as needed. As the spleen is separated from its attachments, the free, cut edge of the greater omentum may be sutured to the free, cut edge of the gastrosplenic ligament. This is most easily performed while the spleen is still attached.

Abdominal wall closure is accomplished in three layers as per the surgeon’s preference. The initial layer includes the peritoneum and periosteum, the second layer consists of the subcutaneous tissues, and the skin is the final layer. Either active or passive drains are recommended between muscle layers to minimize serum accumulation and subsequent wound dehiscence.

Splenorrhaphy and Partial Splenectomy
Lacerations of the spleen, such as may occur during abdominocentesis or minor ruptures of the splenic capsule, may be corrected by splenorrhaphy. Absorbable sutures placed across the defect are usually sufficient to control hemorrhage. Large vessels may need to be individually ligated. Partial splenectomy or splenorrhaphy has not been reported in the horse. Various techniques have been described in humans and canines, including the use of mattress sutures,138-140 stapling devices,71,141 hemostatic (hemostytic) agents,139,140,142 ultrasonic cutting devices,143 CO2 lasers,144 a microwave coagulator,145 an argon-beam coagulator,146 and absorbable mesh consisting of polyglycolic acid147,148 or polyglactin 910.149 We have applied a TA-90 stapling device, followed by application of an oxidized cellulose hemostatic agent (Surgicel, Ethicon, Somerville, NJ), to accomplish partial splenectomy without complication in a horse with a splenic mass (Fig. 32-8).

Closure of the Renosplenic Space
Closure of the renosplenic space has been advocated to prevent recurrence of left dorsal displacement of the large colon.150 More recently, laparoscopic techniques have been described for closing the renosplenic space151,152 (see Chapter 36). The techniques involve suturing the most dorsal visceral surface of the spleen to the renosplenic ligament to eliminate the area between the spleen and the left kidney to which the large colon frequently becomes displaced.150-152 There have been no reported cases of left dorsal displacement after closure of the renosplenic space, and there have been no reported complications of the procedure.

Aftercare
After recovery from anesthesia, the animal should be placed in a stall and hand-walked for the first 7 to 10 days. Body temperature, pulse and respiratory rates, and appetite should be monitored regularly. The incision should also be monitored for signs of heat, swelling, drainage, seroma formation, or infection. Antibiotics may be administered as indicated by clinical signs and the results of bacterial culture and sensitivity testing. Analgesics such as flunixin meglumine, ketoprofen, or phenylbutazone should be administered during recovery and for at least 24 hours after surgery to control pain. Drains placed at the time of surgery should be removed after 2 to 3 days. Drainage and lavage of the incision site should occur if evidence of seroma formation or infection is noted.

Complications
The most serious complication after splenectomy is intrabdominal hemorrhage.96 Incisional complications include drainage, seroma, edema, infection, and dehiscence.79,96,127 Additional complications related to the transthoracic approach include pyothorax, pneumothorax, and pleuritis.96 Complications in humans after splenectomy include atelectasis, pleural effusion, pneumonia, hemorrhage, subphrenic abscess formation, pancreatic fistula and pancreatitis, gastric fistula, thrombocytosis and thrombosis, and sepsis.153

Colic: Diagnosis, 
Preoperative 
Management, and 
Surgical Approaches 
Andrew T. Fischer, Jr.

THE ACUTE ABDOMEN
Horses presented for colic offer equine clinicians one of the most challenging and interesting problems encountered in practice. Rapid and accurate diagnosis can be life saving and professionally satisfying. A thorough but efficient diagnostic evaluation needs to be performed in the presence of emotionally stressed owners who are watching their horse in discomfort, frequently at a referral hospital that is new to them.

Horses presented for colic to a referral hospital fall into one of several groups: immediate surgical management or euthanasia, medical management with further monitoring and possible surgery, or medical management with no possibility of surgery (usually because of financial constraints). It is the clinician’s goal to rapidly and accurately sort the acute abdominal equine patient into the appropriate diagnostic and therapeutic category. A systematic, standardized evaluation facilitates case management.

DIAGNOSIS
History and Signalment
A thorough medical and management history facilitates accurate evaluation of the horse with colic and may serve to guide the selection of additional diagnostic tests specific to the case. The past medical history should be evaluated to see if there are any links to this episode of acute colic. Repetitive bouts of previous colic should make the clinician inquire about previous abdominal surgery, passage of enteroliths, ingestion of sand, or a possible linear foreign body. Management should be examined, with specific attention focused on changes of diet, consumption of water, changes in exercise level, stabiling changes, recent dentistry, or other treatments or medications.

The signalment and history may guide the clinician to a presumptive diagnosis and shape the diagnostic workup. The following are some examples of signalment leading to presumptive diagnosis:

A young racehorse with a recent orthopedic injury should be evaluated for impactions of the large colon or cecum. A broodmare that recently foaled and is now presented with acute severe colic should be evaluated for a large colon volvulus.

Older, obese horses with colic may have a lipoma strangulating the small intestine.

Adult horses, especially Arabian and Quarter Horses, in the southwestern United States, that have mild recurrent colic and are passing mineral oil and scant feces should be evaluated for enterolithiasis. Cribbers should be evaluated for epiploic foramen entrapments.

Foals with a recent history of deworming may have an ascarid impaction.

The use of signalment and history to form a presumptive diagnosis can improve the efficiency of diagnostic evaluations selected. For example, a geriatric horse presented for a high heart rate would be evaluated with ultrasonography before abdominal radiography, because the most likely diagnosis is a small intestinal strangulation rather than an enterolith.

Clinical Observation
Horses presented for colic should be observed in a box stall to appreciate their true level of discomfort. Many normal horses roll when first placed in a new stall and then stand up and shake the bedding off their hair coat, but horses with colic roll and then stand up without shaking off the bedding. The horse should be evaluated for signs of abdominal distention by watching the flank regions. Pain may be exhibited by sweating, muscle fasciculations, and areas of self-inflicted trauma. Evaluation of the facial expression is very important, but this is subjective and not easily described. Flaring of the nostrils, grimacing, and a dull look to the eyes are all indicators of significant pain. It should not be concluded that a horse has no pain after simply observing that it is quiet in standing stocks, because this same horse may roll and exhibit other signs of discomfort once let loose in a box stall.

Signs of Pain
Pain is probably the single most accurate indicator of the need for exploratory surgery in the horse presented for colic, and it must be interpreted with consideration of the horse’s temperament. Draft horses and older horses may be very stoic and may not exhibit obvious signs of pain despite having a lesion that requires surgery. The duration and severity of the pain is also important. Acute severe colic may simply be gas related, but if the pain continues and does not respond to analgesic administration, it is an indicator for surgery. Chronic intermittent low-grade colic is typical of partial intraluminal obstructions (enteroliths) or displacements.

The behavioral manifestations of colic include repetitive lying down and getting up (usually without shaking off bedding), rolling, getting cast, straining to defecate, frequent small amounts of urination, pawing, kicking at their abdomen, looking at the flank region, and assuming a “stretched out” posture. Sweating, playing with the water, tail swishing, and depression are other signs of colic that may be seen, although sweating can also be induced with the administration of some analgesics. Horses with small colon obstructions or other large intestinal impactions may
be noted backing up into the walls of their box stalls. The owner or handler of the horse can be of valuable help in interpreting an individual horse’s expression of pain and should be consulted.

Pain is frequently evaluated by the severity, duration, and quality of response to administered analgesic medications and by the horse’s response to environmental factors. Mild colic pain may be hidden by handling or hand-walking. Administration of flunixin meglumine will typically keep the horse comfortable for 8 to 12 hours or longer. Moderate pain is usually manifested by some of the behavior patterns mentioned previously—it can be temporarily interrupted by hand-walking, but return when the horse is replaced in its box stall. Relief from analgesics may last for several hours but redosing is frequently required and is usually an early indicator of the need for surgical intervention. Moderate to severe pain is noted by very short or no response to administered analgesics, and the horse is uncontrollable even with constant walking or handling. Horses with uncontrollable pain are a danger to themselves and to handlers and should be treated as such. Horses with colic that is likely to need surgery, frequently stay comfortable for 1 hour or less after the administration of xylazine (0.2 to 0.5 mg/kg IV).

All horses presented for colic should have a complete physical examination performed. It should include determination of temperature, heart and respiratory rates, pulse quality, mucous membrane assessment with capillary refill time, and auscultation of the thorax and abdominal cavities. An elevated body temperature should be thoroughly evaluated prior to surgery, because few operable lesions are associated with fever. Enteritis, colitis, and respiratory disease need to be ruled out in horses presented for colic and fever. It is important to remember to obtain the temperature prior to rectal examination, as the access to air resulting from the examination will lower the rectal temperature. Subnormal temperatures can be an indicator of severe shock, or they may be merely spurious. Heart rate and respiratory rate frequently increase with pain, but they may remain normal because of analgesic administration. An elevated heart rate often reflects cardiovascular compromise and impending endotoxic shock. Elevated respiratory rates may be seen with colic but also with respiratory disease. Pulse quality and mucous membrane assessment provide further evaluation of the cardiovascular system.

Auscultation
Abdominal auscultation is a part of the examination of the horse with colic. However, normal gastrointestinal sounds may be heard in horses with colic requiring surgery, and borborygmis may be absent in normal horses that have been sedated. It is important to listen for several minutes to allow a full cycle of contractions of the bowel to occur. Increased abdominal sounds may be heard in horses with impending colitis or enteritis. The presence of sand within the gastrointestinal tract may be determined by listening to the ventral abdominal wall caudal to the xiphoid process and are described as being similar to the sounds heard when listening to a seashell. An absence of gastrointestinal sounds may be caused by administration of a sedative, or it may imply that surgery is needed. In general, an absence of intestinal noises is more significant than the presence of sounds in evaluating the horse with the acute abdomen, and it usually implies significant disease.

Gas pockets and tympany may be localized by simultaneous auscultation and percussion. Areas of tympany are more reliably located in the right paralumbar fossa, where the cecum and colon are in direct contact with the body wall. Auscultation of the thorax is important to rule out thoracic disease in horses that are exhibiting signs of colic. Colic may be suspected in horses with bronchopneumonia (see Chapter 48). Pleural effusion can be detected by auscultation, but in horses with colic, the heart sounds radiate over a larger area than is typical and decreased lung sounds are heard ventrally.

Rectal Examination
Abdominal palpation per rectum can offer important information to the clinician evaluating the horse presenting with colic. A systematic examination should be performed on each horse. Restraint of the horse in stocks and sedation or the administration of spasmylytic agents may improve the diagnostic yield and the clinician’s safety. Abnormalities noted on abdominal palpation per rectum can include distended or edematous small intestine, small intestinal impactions, large colon distention, impaction or edema, displacements of the large colon, space-occupying masses (abscesses, neoplasia), abnormalities of the urogenital tract (uterine torsion or hemorrhage into the broad ligament), inguinal herniation, and free abdominal gas associated with visceral rupture. Enteroliths are rarely felt because of their location in the transverse colon or proximal small colon, but they are occasionally found. (Abdominal palpation during laparoscopic observation is a useful training tool for students and clinicians.)

Nasogastric Intubation
Nasogastric intubation should be performed on all horses presented for colic. When there is gastric dilation (either primary or secondary), it may prevent gastric rupture and save the life of the horse. Large-bore stomach tubes facilitate recovery of gastric fluid because they are less likely to become occluded by gastric contents than are smaller tubes. Stomach tubes are routinely left in place during anesthesia for colic surgery to facilitate gastric decompression and decrease uncontrolled gastric reflux (which can cause pharyngeal burns or pneumonia if aspirated). Flushing of fluid into the nasogastric tube can start a siphoning action to empty the stomach. Effective emptying of the stomach can be verified by ultrasonography or gastroscopy.

Clinical Pathology
Horses presented for colic are frequently operated on despite minimal clinical pathologic data because of the emergency nature of the acute abdominal crisis and the decreased levels of staff available in the middle of the night. Baseline data (packed cell volume [PCV], total protein) are easily obtained to assess the hydration status. Decreased total protein with an elevated PCV indicates protein loss and dehydration, which together indicate a poor prognosis. However, modern laboratory equipment has become
simpler to use, and if full electrolyte panels and serum chemistries are available at the time of evaluation, they should be utilized. Electrolyte levels and blood gas status may be assessed to guide fluid replacement prior to and during anesthesia to minimize complications (see Chapters 3 and 8). White blood cell counts are useful if available. Decreased white blood cell values should make the clinician evaluate the horse for the presence of colitis or a possible visceral rupture. Creatinine levels should be evaluated for the possibility of renal disease or dehydration. Elevations of gamma-glutaryl-transferase may indicate liver disease. Horses with colonic displacements may have elevated liver enzymes because of biliary outflow obstruction.

**Abdominocentesis**

Abdominocentesis is frequently performed in horses presented for colic when a diagnosis has not been reached by other methods. It is not generally necessary when a decision has already been made for surgical intervention, unless the clinician is concerned about visceral rupture. Multiple methods exist for obtaining abdominal fluid. The most dependent part of the abdomen is prepared for the abdominocentesis on the midline by clipping the hair and preparing with antibacterial soap. Local anesthetic is infiltrated into the skin and linea alba. A no. 15 blade is used to make a skin incision and stab into the linea alba. A teat cannula (7.5 cm) or bitch catheter is then forced into the abdominal cavity through the stab incision and punctures the peritoneum. Alternatively, an 18-gauge needle may be used to obtain the abdominal fluid, and only local anesthesia is necessary. The abdominal fluid should be collected into a serum tube without any ethylenediamine-tetra-acetic (EDTA) for total protein (because total protein may be elevated when collected into an EDTA tube) and into an EDTA tube for cytology and cell counts. The needle or cannula may be left in place for several minutes to obtain fluid.

Abdominocentesis carries the risk of bowel laceration or enterocentesis, or amniocentesis in the term mare. Horses with sand accumulations are particularly at risk because the weight of the colon holds it in apposition to the ventral body wall. Abdominal ultrasonography can be used to localize accumulations of abdominal fluid and select alternative abdominocentesis sites. Abdominocentesis can also be dangerous to the collector if the horse decides to kick, so caution is always indicated. Additionally, the needle technique should be used with caution in foals because the distended bowel is easily punctured.

Analysis of abdominal fluid includes cell counts, cytology, total protein, and in some centers biochemical analysis. Normal white blood cell count in abdominal fluid is less than 10,000/µL in adults and less than 1500 cells/µL in foals, but this value varies between clinics. Peritoneal protein collected into serum tubes is usually below 2.0 g/dL. Cytologic evaluation of the abdominal fluid should include examination for degeneration of cells and classification of cell populations, as well as for the presence of bacteria. It is not unusual for a horse to need an exploratory celiotomy despite normal abdominal fluid analysis data, and the reverse can be true (normal horse with abnormal abdominal fluid analysis data). The results of abdominal fluid analysis are less clear in horses that have recently undergone an exploratory celiotomy, castration, or laparoscopy, because they have elevated white blood cell counts and total proteins.

**Ultrasonography**

Abdominal ultrasonography has become a routine part of the diagnostic evaluation of the horse presented for colic, because it offers information that cannot be obtained with other diagnostic methods. The horse’s abdomen is sprayed with alcohol to improve acoustic coupling, and a systematic examination is performed on both sides of the horse from the line of the diaphragmatic reflection down to ventral midline. A lower-frequency probe (2 to 3.5 MHz) is employed in adult horses to allow visualization of deeper structures. Higher-frequency probes may be used in smaller horses and foals for more detail. The stomach can be evaluated for the presence of gastric fluid or squamous cell carcinoma. The small intestine can be assessed for the presence of movement, mural thickness, and dilation. Normal small intestinal wall thickness is 3 mm or less. In horses with enteritis, the small intestinal wall is frequently thickened, motionless, and full of fluid or ingesta (Fig. 33-1). When there is intestinal obstruction, the small intestine is distended, fluid filled, and hypomotile (Fig. 33-2). Ultrasonography has been demonstrated to be more accurate than abdominal palpation per rectum for the identification of small intestinal strangulations. The strangulated intestine is most frequently located in the ventral abdominal cavity. Other small intestinal lesions that are found on ultrasonography include intussusceptions and inguinal herniation. Lesions involving the cecum may be imaged and include cecocolic and cecocecal intussusceptions. Large colon torsions may be diagnosed by imaging the large colon from the ventral abdomen, with a transmural thickness of 9 mm or greater indicating a likely diagnosis (with a sensitivity of 67%). Intra-abdominal fluid accumulations and masses involving intra-abdominal viscera may also be imaged.

Ultrasonography is not useful for the detection of enteroliths because of their location and because the acoustic echo from a stone and a gas shadow are similar.

**Radiography**

Abdominal radiography is very valuable in diagnosing enteroliths and sand accumulations (see Fig. 36-11) in adult horses and is routinely used in areas of the United States where these problems are endemic. However, the failure to image an enterolith does not mean that one is not present, as false negatives do occur. Enteroliths in the small colon are more difficult to image in the horse that is distended. Sand accumulations are easily imaged in most horses in the ventral abdomen, even with low-powered radiograph machines. Calcifications around linear foreign bodies are also occasionally demonstrated on radiographs. Diaphragmatic hernias may be demonstrated on abdominal or thoracic radiographs, but it is more common to discover this defect at surgery.

Abdominal radiography can offer more detail in foals and small horses. Noncontrast radiography is useful in the neonate with colic and should be supplemented by ultrasonography. Gastric dilation and small intestinal and large intestinal distention may all be diagnosed on noncontrast
abdominal radiography. Contrast media consisting of 30% wt/vol barium sulfate radiography may be administered either orally or rectally and is useful for delineating obstructions or delays in transit. Meconium or other obstructions of the small and large colon, as well as segmental atresias, are readily demonstrated with retrograde contrast radiography.

**DECISION FOR SURGERY**

The decision to perform an exploratory celiotomy in the horse with colic requires consideration of the diagnostic evaluation and all the other information available to the clinician. In most cases, the decision can be based on the available information and is fairly clear. Horses that are not
in pain require further observation and diagnostic evaluation to reach the proper decision. Because of improvements in preoperative stabilization and anesthesia, exploratory celiotomy is less dangerous in terms of morbidity and mortality. Early surgical intervention, even if it is unnecessary (e.g., the lesion found may have been amenable to medical management) is less dangerous to the horse with colic than delayed surgical intervention that results in visceral rupture. Exploratory celiotomy should be strongly considered in horses with colic that have any of the following conditions:

- Persistent or recurrent pain despite the administration of analgesics
- Presence of an enterolith on abdominal radiography
- Presence of distended edematous small intestine without motility on ultrasonography
- Physiologic deterioration despite attempted stabilization with intravenous fluids and other supportive treatments
- Progressive abdominal distention
- Persistent gastric reflux
- Abdominal palpation findings of small intestinal distention, colonic displacement, or very firm intraluminal mass (enterolith or foreign body)
- Serosanguineous abdominal fluid with elevated protein

ANCILLARY DIAGNOSTIC AIDS

Endoscopy

Endoscopic evaluation of the gastrointestinal tract is limited to the esophagus, stomach, duodenum, rectum, and distal small colon by the length of commercially available endoscopes. A 3-m working-length endoscope is commonly used in equine practice. Gastroscopy is useful for the detection of gastric ulcers, gastric impactions, and gastric squamous cell carcinoma. Gastric ulcers are frequently a secondary lesion in horses with colic and indicate the need for further diagnostic workup if antiulcer medication does not alleviate signs of discomfort. Examination of the distal small colon and rectum is most commonly performed in horses with suspected rectal tears or palpable intraluminal masses in these areas.

Laparoscopy

Laparoscopy can be a useful diagnostic tool in horses with both acute and chronic colic. In horses with acute colic, laparoscopy can confirm the need for an exploratory celiotomy or euthanasia. A sensitivity of 82% was found for horses with acute colic, coupled with a specificity of 66%, indicating that if a lesion was found at laparoscopy, it was the likely cause but a significant number of lesions were missed.\(^5\) It is uncommon for a standing laparoscopy to be therapeutic in the horse with acute colic. When performing laparoscopy in the horse with acute colic, it is important to carefully enter the abdominal cavity to avoid penetration of a gas-distended viscus. An open-approach laparoscopy may be performed in horses with abdominal distention. In cases of chronic colic, the horse may be fasted and good visualization of the abdominal cavity may be obtained during diagnostic laparoscopy. The sensitivity for lesion identification in horses with chronic colic declined to 63% with a specificity of 17%. Laparoscopy may be performed in either the standing or the anesthetized horse, depending on where the suspected lesion is located.

Laparoscopy has been used to diagnose trauma after foaling (tears of the small colon mesocolon, uterine rupture, hemorrhage into the broad ligament), abdominal cavity trauma (penetrating wounds), and splenic disease (tumors, hematomas, and ruptures). It also helps identify adhesions (Fig. 33-3), small intestinal strangulations, large colon displacements (Fig. 33-4), visceral rupture, and abdominal neoplasia.\(^5\)

Technique for Diagnostic Standing Laparoscopy

The horse is restrained in standing stocks with the tail secured to prevent contamination of the flank region during surgery. A sedative analgesic combination (e.g., xylazine 0.4 mg/kg) is administered via intravenous catheter. Anesthetic induction and maintenance are performed using volatile anesthetic\(^10\). The horse is then anesthetized with an intravenous catheter placed in the cephalic or median antebrachial vein for administration of general anesthesia. The abdomen is then prepared for surgery with the use of antiseptic solution. A skin incision is made over the epigastric region, and the peritoneal cavity is entered through a midline or paramedian incision. The peritoneal cavity is entered with a blunt trocar and the abdomen is insufflated with carbon dioxide to a pressure of 12–15 mm Hg. The abdomen is then inspected for evidence of visceral rupture, adhesions, or other lesions. If no lesions are found, a metal grasper or forceps is used to grasp the mesocolon of the small colon and deliver it through the incision. The mesocolon is then examined for evidence of tearing or perforation. If no lesions are found, the abdomen is closed in layers and the horse is allowed to recover from anesthesia. If lesions are found, they are then treated according to their nature and severity. It is important to carefully inspect the abdominal cavity for evidence of visceral rupture, adhesions, or other lesions. If no lesions are found, the abdomen is closed in layers and the horse is allowed to recover from anesthesia. If lesions are found, they are then treated according to their nature and severity.
to 0.6 mg/kg IV and butorphanol tartrate [0.022 mg/kg]) is administered, and both flank regions are prepared for aseptic surgery. Additional analgesics may be administered as needed during the procedure. Local anesthesia (10 to 30 mL) is infiltrated into the sites of trocar introduction both subcutaneously and intramuscularly. The primary site of trocar introduction is usually at the dorsal margin of the internal abdominal oblique muscle midway between the last rib and the tuber coxae. Accessory portals are established above or below this for instrument introduction. The use of adherent drapes is less traumatic to the standing horse than the use of penetrating towel clamps, unless all sites are infiltrated with local anesthesia.

The flank regions should have been previously evaluated for the presence of adherent viscera (via ultrasonography) or other contraindications for laparoscopic portal placement in that region. A 1.5-cm stab incision is made through the skin and underlying fascia to allow introduction of the first laparoscopic trocar or cannula (15 cm in length) assembly. The assembly is inserted aiming at the contralateral coxo-femoral joint until resistance decreases. The laparoscopic telescope is then inserted and penetration into the abdominal cavity is confirmed or the laparoscope is found to still be in the retroperitoneal space. If the telescope is in the retroperitoneal space, a quick thrust with the 30-degree telescope will tear the peritoneum. Correct placement into the abdominal cavity is confirmed visually and by being able to freely move the laparoscope without patient discomfort. Insufflation with carbon dioxide to 10 to 15 mm Hg is commenced. Once the abdomen has been insufflated, systematic exploration should occur. Additional portals may be placed to allow introduction of instruments to facilitate manipulation of viscera.

When evaluating the left side of the abdomen, the first structure typically seen is the nephrosplenic ligament with the spleen and associated perirenal fat (Fig 33-5). The mesenteric root is then seen, as are sections of the small intestine and the colon. Passing the laparoscope over the nephrosplenic ligament cranially, the lateral and dorsal surface of the stomach is examined. The diaphragm and left part of the liver are seen further cranially. The evaluation of the caudal abdomen includes visualization of the urogenital organs (the ovary, uterus, and broad ligament in the mare, or the vas deferens and mesorchium in the male, and the urinary bladder). The rectum is noted dorsal to the urinary bladder. The inguinal rings may be evaluated.

The right side of the abdomen is typically evaluated by a separate entry portal in the right paralumbar fossa. The base of the cecum and duodenum are seen when first entering the abdomen. Looking above the duodenum, the right renal outline is seen. The liver is located ventrad and cranial to this, and the epiploic foramen may be entered. Looking caudally, the root of the mesentery is seen, as are sections of the small and large intestine. The right side of the urogenital tract is evaluated similarly to the left side. The use of a biopsy forceps or chambers catheter through a separate portal is helpful to probe organs and move viscera to improve visualization.

At the termination of the laparoscopic evaluation, the valves in the cannula assembly are held open to allow as much of the insufflating gas as possible to leave the abdominal cavity to improve postoperative patient comfort. The skin is sutured and nonsteroidal anti-inflammatory agents are administered if necessary.

**PREOPERATIVE MANAGEMENT OF THE ACUTE ABDOMEN**

**Pain Control**

Alleviation of pain in the horse with colic is important, but it must be carried out carefully, because if excessive pain relief disguises colic that needs surgery, visceral rupture may occur. Flunixin meglumine (0.5 to 1.1 mg/kg) may be administered as a presurgical anti-inflammatory drug and to help protect against the effects of endotoxemia. Repetitive dosing can mask signs that would otherwise dictate surgical intervention. Most horses that are referred to surgical centers have already been given flunixin meglumine, and more should not be administered in the hospital unless surgery has been performed or no surgical option is available.

Xylazine (0.2 to 0.4 mg/kg IV) is a potent analgesic and may be used to control moderate to severe abdominal discomfort, with a reasonably short duration of action. It is particularly useful during the evaluation period of the horse with colic to allow diagnostic procedures to be performed, because it has a rapid onset of action with a short duration of pain relief. Horses that require exploratory celiotomy typically begin demonstrating signs of colic in 30 to 60 minutes after administration of xylazine. If additional analgesia or duration of sedation is necessary, butorphanol tartrate may be administered (0.011 to 0.022 mg/kg IV).

Repetitive dosing of xylazine or other analgesics is rarely indicated in horses that have a surgical option. Use of longer-acting sedatives or analgesics such as detomidine should be reserved for horses without option of surgical intervention.

**Preoperative Preparation**

Once the decision to perform surgery has been made, induction of anesthesia may occur. An intravenous catheter should be placed to allow high-volume fluid replacement...
if necessary. The horse’s mouth should have been washed out and a nasogastric tube placed that will remain for the duration of surgery. It is important to have stabilized the horse as well as possible preoperatively with intravenous fluids (see Chapter 8). Preoperative antibiotics and tetanus prophylaxis should be provided. The operating room with necessary supplies should be set up in advance to minimize wasted anesthesia time. Preparation of the ventral abdominal wall takes place under general anesthesia and is usually more efficient and safer than attempting to prepare the horse while still standing.

**APPROACHES TO THE ABDOMEN**

**Ventral Midline Celiotomy**

Ventral midline celiotomy (VMC) (Fig. 33-6) through the linea alba is the most common approach for equine abdominal surgery because it allows exteriorization of 75% of the intestinal tract (Fig. 33-7). The stomach, duodenum, distal ileum, dorsal body and base of the cecum, distal right dorsal and transverse colon, and terminal descending colon are the only segments that cannot be exteriorized. The VMC creates minimal hemorrhage, is easy to extend, and has strong fibrous tissue for closure.

The linea alba is a combination of the median fibrous raphe of the aponeuroses of the external abdominal oblique muscle, the internal abdominal oblique muscle, and the transverse abdominal muscle extending from the xiphoid process to the prepubic tendon. Histologically, the linea alba consists of dense connective tissue composed of sheets of collagen bundles and fibroblasts. The fibers of the sheets cross between one another, adding to its mechanical strength.

In horses, the thickness of the cranial part of the linea alba may reach 0.3 mm, whereas the caudal part reaches 1 cm. The midline incision is made as long as necessary to complete the exploratory surgery (averaging about 30 cm in the adult horse). The incision should be large enough to allow exteriorization of necessary viscera and not put excessive pressure on the intestine (which would increase the risk of iatrogenic tears). The time saved in the procedure and the increased safety of a larger incision more than compensate for the extra several minutes spent suturing a longer incision. The incision through the linea should begin at the umbilicus where it is the thickest and continue cranially, avoiding the rectus abdominis muscle.

Closure techniques of the celiotomy incision vary between surgeons and are usually a matter of personal preference. The optimal distance that a suture should be placed from the incisional edge of the linea alba in horses is 1.2 to 1.5 cm. Excessive tension on sutures causes microscopic
tissue necrosis and is the most common surgical error made during closure of the linea alba.11

Ventral Paramedian Approach
The ventral paramedian incision, the second most common approach used in colic operations, is made 10 cm lateral to the midline (see Fig. 33-6). The incision may be made on either the right or left of midline through the rectus abdominis muscle, which creates a thicker border to the incision than the ventral midline approach but does not significantly limit surgical exposure of the abdominal cavity. The deep and superficial epigastric vessels may be encountered during this incision and should be avoided if possible. The ventral paramedian incision typically hemorrhages more than the linea alba incision, but this does not seem to generate any clinical problems and the wound generally heals well. Some surgeons favor the paramedian incision, particularly if wound healing is thought to be compromised, because fewer hernias are observed to be associated with this incision. Some surgeons prefer to use the paramedian incision when relaparotomy is required. It is better to avoid a previous linea alba incision if there are signs of excessive inflammation, infection, or possible adhesions. Closure of the paramedian incision involves suturing of the external fascia of the rectus abdominis sheath. Suturing of the muscle belly does not appear to contribute to the strength of the closure.

Flank Approach
A standing flank approach to the abdomen is easily performed but less easily applied to the correct clinical situation (Fig. 33-8). The small colon is the most accessible part of the intestinal tract approached from the flank. A nondistended large colon can be exteriorized through a flank incision (1), transverse flank incision (2). TC, tuber coxae. (Redrawn from Adams SB: Surgical approaches to the equine abdomen, Vet Clin North Am Large Anim Pract 1982;4:103.)

Figure 33-8. Abdominal approaches through the flank: paralumbar incision (1), transverse flank incision (2). TC, tuber coxae.

(Received from Adams SB: Surgical approaches to the equine abdomen, Vet Clin North Am Large Anim Pract 1982;4:103.)

standing flank laparotomy is too limited for it to serve as a routine abdominal exploratory approach.

The most commonly used approach for flank laparotomy is the modified grid approach. The horse is restrained in standing stocks with the tail tied, and the flank region is prepared for aseptic surgery. A sedative-and-analgesic combination is administered, and local anesthesia is infiltrated subcutaneously and intramuscularly at the planned site of incision. The skin is sharply incised in a vertical line midway between the last rib and the tuber coxae, starting dorsal to the palpable dorsal edge of the internal abdominal oblique and continuing ventrally (see Fig. 33-8). The external abdominal oblique muscle is subsequently sharply divided. The internal abdominal oblique and transverse abdominal muscles are bluntly divided parallel to their fiber direction, exposing the peritoneum, which is then punctured, giving access to the abdominal cavity. Closure of the incision is by muscle apposition with absorbable sutures for the deep layers and subsequent closure of the external abdominal oblique muscle layer for a second layer. The subcutaneous tissues may be included in this layer or sutured separately. The skin is sutured or stapled.

Inguinal Approach
The inguinal approach is used in conjunction with a ventral midline incision when operating on stallions with inguinal or scrotal hernias (see Fig. 33-6). The inguinal approach alone usually does not allow a thorough exploration and decompression of the nonherniated bowel. The inguinal herniorrhaphy often is combined with unilateral castration of the affected testicle. Most hernias are of the indirect type with the vaginal tunic intact. After repair of the intestinal lesion, the tunic can be ligated to bolster the inguinal closure. The external inguinal ring is closed using 2 or 3 polyglactin 910 in a simple-continuous or a simple-interrupted pattern, with sutures placed 1.5 to 2.0 cm apart. The subcutaneous tissues and skin are closed as separate layers. (For more details on anatomy and surgery of the inguinal ring, see Chapters 38 and 65) Alternatively, laparoscopy allows internal repair of the inguinal ring damaged by herniation through mesh secured by staples or laparoscopic suturing techniques.13

REFERENCES
Intestinal injury, although typically associated with ischemic lesions, occurs during any obstructive intestinal disease to varying degrees depending on the type of obstruction and the extent of vascular compromise. In addition, in some instances, the intestinal lumen is patent, but there is vascular compromise—for example, in nonstrangulating infarctions. Intestinal obstructive lesions are classified as either simple or strangulating obstructions. A great deal of work has been done to assess the level of injury encountered with these lesions at surgery and during the postsurgical phase following correction and reperfusion of these lesions. Although more is known about mucosal injury than about injury encountered in other intestinal layers, it is clear that substantial injury also occurs at the levels of the serosa and the muscularis, which very likely contributes to postoperative complications such as adhesion formation and ileus. Understanding the pathophysiology of these lesions allows the surgeon to more adequately perform surgical and postoperative procedures to optimize patient survival. For example, attention has been focused on the development of intestinal injury during reperfusion, and the possibility of inhibiting these lesions with various treatments. Furthermore, to combat the postoperative complication of serosal inflammation and secondary adhesion formation, surgeons have adopted a number of new treatments.

**CHAPTER 34**

Principles of Intestinal Injury and Determination of Intestinal Viability

Anthony T. Blikslager

**TYPES OF OBSTRUCTION**

**Simple Obstruction**

Although simple obstruction, most commonly caused by an intraluminal impaction, does not initially result in intestinal injury, studies show that, as distention progresses, mucosal lesions similar to those encountered during ischemic injury occur. More specifically, there are critical intraluminal pressure levels beyond which intramural vascular compression takes place, reducing tissue perfusion. Furthermore, direct compression of the intestinal wall by obstructive masses may lead to a lesion that has the appearance of an infarction as a result of occlusion of the local arterial supply. Causes of these compressive lesions tend to be hard masses such as enteroliths or fecaliths, which, if not recognized during early lesion formation, may result in intestinal rupture. Injury caused by progressive intestinal distention, particularly in the case of fluid accumulation proximal to a small intestinal obstruction, is more difficult to recognize clinically than compressive infarctions, but nonetheless it is important to be aware of it to minimize postsurgical morbidity.

**Strangulating Obstruction**

Strangulating obstruction results from simultaneous occlusion of the intestinal lumen and its blood supply. The clearest examples of such lesions include large colon volvulus, and strangulation of the small intestine within an internal hernia or via an abnormal band of tissue such as the stalk of a pedunculated lipoma. The degree of injury attributable to occlusion of the blood supply depends on the nature of vascular occlusion. In most instances, the veins are occluded earlier in the course of strangulating obstruction than the arteries because of their thinner and more compliant walls. This results in a disparity in blood flow during the early phases of strangulating obstruction, with continued pumping of arterial blood into the intestinal wall, which, in the absence of patent outflow, causes a hemorrhagic lesion termed **hemorrhagic strangulating obstruction**. This results in not only ischemic injury but also tremendous congestion of the tissues. Alternatively, the strangulation may exert sufficient pressure on the veins and arterial supply that both are occluded simultaneously, resulting in so-called...

Principles of Intestinal Injury and Determination of Intestinal Viability
Anthony T. Blikslager

Intestinal injury, although typically associated with ischemic lesions, occurs during any obstructive intestinal disease to varying degrees depending on the type of obstruction and the extent of vascular compromise. In addition, in some instances, the intestinal lumen is patent, but there is vascular compromise—for example, in nonstrangulating infarctions. Intestinal obstructive lesions are classified as either simple or strangulating obstructions. A great deal of work has been done to assess the level of injury encountered with these lesions at surgery and during the postsurgical phase following correction and reperfusion of these lesions. Although more is known about mucosal injury than about injury encountered in other intestinal layers, it is clear that substantial injury also occurs at the levels of the serosa and the muscularis, which very likely contributes to postoperative complications such as adhesion formation and ileus. Understanding the pathophysiology of these lesions allows the surgeon to more adequately perform surgical and postoperative procedures to optimize patient survival. For example, attention has been focused on the development of intestinal injury during reperfusion, and the possibility of inhibiting these lesions with various treatments. Furthermore, to combat the postoperative complication of serosal inflammation and secondary adhesion formation, surgeons have adopted a number of new treatments.

TYPES OF OBSTRUCTION

Simple Obstruction

Although simple obstruction, most commonly caused by an intraluminal impaction, does not initially result in intestinal injury, studies show that, as distention progresses, mucosal lesions similar to those encountered during ischemic injury occur. More specifically, there are critical intraluminal pressure levels beyond which intramural vascular compression takes place, reducing tissue perfusion. Furthermore, direct compression of the intestinal wall by obstructive masses may lead to a lesion that has the appearance of an infarction as a result of occlusion of the local arterial supply. Causes of these compressive lesions tend to be hard masses such as enteroliths or fecaliths, which, if not recognized during early lesion formation, may result in intestinal rupture. Injury caused by progressive intestinal distention, particularly in the case of fluid accumulation proximal to a small intestinal obstruction, is more difficult to recognize clinically than compressive infarctions, but nonetheless it is important to be aware of it to minimize postsurgical morbidity.

Strangulating Obstruction

Strangulating obstruction results from simultaneous occlusion of the intestinal lumen and its blood supply. The clearest examples of such lesions include large colon volvulus, and strangulation of the small intestine within an internal hernia or via an abnormal band of tissue such as the stalk of a pedunculated lipoma. The degree of injury attributable to occlusion of the blood supply depends on the nature of vascular occlusion. In most instances, the veins are occluded earlier in the course of strangulating obstruction than the arteries because of their thinner and more compliant walls. This results in a disparity in blood flow during the early phases of strangulating obstruction, with continued pumping of arterial blood into the intestinal wall, which, in the absence of patent outflow, causes a hemorrhagic lesion termed hemorrhagic strangulating obstruction. This results in not only ischemic injury but also tremendous congestion of the tissues. Alternatively, the strangulation may exert sufficient pressure on the veins and arterial supply that both are occluded simultaneously, resulting in so-called
**ischemic strangulating obstruction.** This results in rapid degeneration of the mucosa.6

Clinically, hemorrhagic or ischemic strangulating obstruction may be noted in horses with large colon volvulus. In horses with a 360-degree large colon volvulus, hemorrhagic strangulating obstruction is most frequently noted, particularly if there is ample ingesta within the lumen to reduce how tightly the intestine twists around its mesenteric axis. However, there are also cases of ischemic strangulating obstruction, particularly in horses with a volvulus that exceeds 360 degrees, or in horses with little ingesta in the lumen.7

**Nonstrangulating Infarction**

Nonstrangulating infarction most commonly occurs secondary to cranial mesenteric arteritis caused by migration of Strongylus vulgaris,8 which has become a relatively rare disorder since the advent of broad-spectrum anthelmintics. Although thromboemboli have been implicated in the pathogenesis of this disease, careful dissection of naturally occurring lesions has not revealed the presence of thrombi at the site of intestinal infarctions in most cases. These findings suggest that vasospasm plays an important role in this disease.8 Any segment of intestine supplied by the cranial mesenteric artery or one of its major branches may be affected, but the distal small intestine and large colon are more commonly involved.8 These lesions have no obvious cause of obstruction, but they have clearly demarcated regions of degeneration or necrosis, depending on the extent of vascular occlusion.

**MECHANISMS OF INJURY**

**Luminal Distention**

Investigators have examined the role of small intestinal intraluminal distention and decompression on the microvasculature. In one study, distention of the jejunum to an intraluminal hydrostatic pressure of 25 cm H2O for 120 minutes resulted in a significant reduction in the number of perfused vessels in the seromuscular and mucosal layers, and vascular perfusion remained abnormal after decompression.2 This in turn led to epithelial sloughing, similar to that noted in ischemic lesions.3 Alternatively, earlier studies indicated that there was no histologic evidence of epithelial sloughing with pressures up to 18 cm H2O for 4 hours, although the authors did note mucosal and submucosal edema.1 Thus, it is clear that the nature of mucosal lesions depends on the degree of intraluminal pressure. In experimental studies on the effects of distention, the seromuscular layer appeared to be more severely affected, and it had evidence of mesothelial cell loss, neutrophil infiltration, and edema that progressed after decompression, suggesting reperfusion injury in this tissue.10

This type of inflammatory seromuscular lesion has also been noted in studies of the proximal resection margins of naturally occurring small intestinal strangulating obstructions, indicating that distention leads to seromuscular injury proximal to obstructive lesions, despite the fact that this intestine may appear grossly normal.11 Experimentally, this seromuscular injury and inflammation leads to adhesion formation. Thus, foals subjected to intraluminal distention of a segment of jejunum to 25 cm H2O for 2 hours in one study developed bowel-to-bowel and bowel-to-mesentery adhesions within 10 days of the surgical procedure.12 Similar experiments in the large colon have revealed that the colon is far more resistant to seromuscular injury than the small intestine.10

**Mucosal Ischemic Injury**

To understand how the mucosa becomes injured during ischemia, critical anatomic features of the mucosa have to be taken into consideration. In the equine small intestine, the villus tip is the region most susceptible to ischemia, largely because of the countercurrent exchange mechanism of blood flow in the small intestinal villus.13 This countercurrent exchange mechanism is attributable to the vascular architecture, which consists of a central arteriole that courses up the core of the villus, arborizes at the tip, and is drained by venules coursing down the periphery of the villus.14 As oxygenated blood enters the central arteriole, oxygen diffuses across the wall of the arteriole, through the interstitial tissues, and into the peripheral venules, which are flowing in the opposite direction. Although this enhances intestinal absorption, it short-circuits the oxygen supply, resulting in a villus tip that is relatively hypoxic even under normal conditions. Countercurrent exchange is exacerbated when the rate of the arterial blood flow is reduced, essentially providing more time for the oxygen to diffuse out of the arteriole across to the venules. When the arterial flow is reduced to a critically low level, the tip of the villus becomes absolutely hypoxic, with attendant epithelial injury.13,15 This mechanism may explain why the small intestinal mucosa is more susceptible to ischemic injury than the colon, which has no villi. For example, the time required to produce severe morphologic damage to the equine colon is approximately 25% longer than that for the small intestine.16

Mucosal epithelium is particularly susceptible to hypoxic injury because of the relatively high level of energy required to fuel the Na+/K+-ATPase mechanism that regulates epithelial ion and nutrient transport. The first biochemical event to occur during hypoxia is a loss of oxidative phosphorylation. The resulting diminished ATP concentration causes failure of the energy-dependent Na+/K+-ATPase mechanism, resulting in intracellular accumulation of sodium and water. The pH of the cytosol drops as lactic acid and inorganic phosphates accumulate from anaerobic glycolysis, which damages cell membranes and results in their detachment from the basement membrane.17

As epithelium separates from the underlying basement membrane in the small intestine, a fluid-filled space termed Grüenhagen’s space forms at the tip of the villus.15 The fluid accumulation exacerbates epithelial separation from the basement membrane. Subsequently, epithelium progressively sloughs from the tip of the villus (Fig. 34-1) toward the crypts, which are the last component of the intestinal mucosa to become injured.18-20 The relative resistance of the crypts to injury probably relates to their vascular architecture, since crypts receive a blood supply that is separate from the vasculature involved in the villus countercurrent exchange mechanism. The early morphologic changes observed in the equine large colon during ischemia are similar to those described in the equine small intestine, with
initial loss of the more superficially located surface cells, followed by cellular injury and sloughing within the crypts.16,21

Reperfusion Injury

Events that culminate in reperfusion injury in the small intestine are initiated during ischemia when the enzyme xanthine dehydrogenase is converted to xanthine oxidase, and its substrate, hypoxanthine, accumulates as a result of ATP utilization.22,23 However, there is little xanthine oxidase activity during ischemia, because oxygen is required as an electron acceptor. During reperfusion, xanthine oxidase rapidly degrades hypoxanthine in the presence of oxygen, which acquires a single additional electron, producing superoxide.22 Superoxide contributes to oxidative tissue damage, but this reactive oxygen metabolite is relatively lipid insoluble, limiting the level of injury.

However, the more important role for superoxide is in the generation of neutrophil chemoattractants.24,25 Superoxide interacts with lipid membranes, triggering arachidonic acid metabolism and generation of lipid neutrophilic chemoattractants such as leukotriene B4. Because of the critical role of xanthine oxidase, inhibition of this enzyme in feline studies of intestinal ischemia/reperfusion injury prevented infiltration of neutrophils and subsequent mucosal injury.25,26 Studies went on to show that reperfusion injury could be inhibited at several levels of the reperfusion cascade, including scavenging superoxide with superoxide dismutase, inhibiting neutrophil infiltration with monoclonal antibodies directed against neutrophil adhesion molecules, and scavenging neutrophil-released reactive oxygen metabolites.22,25 Researchers were initially optimistic that this would provide practical therapeutic interventions, because many of the treatments tested, including the xanthine oxidase inhibitor allopurinol, could potentially be administered prior to reperfusing an ischemic lesion at surgery (Fig. 34-2).

Unfortunately, treatment of mucosal reperfusion injury has not proven to be highly effective in most cases of strangulating obstruction. One important reason for this is that strangulating obstruction induces maximal mucosal injury during the ischemic phase, as compared with studies in laboratory animals in which “low-flow” ischemia was used.27 The latter involves reduction but not cessation of arterial flow, which induces relatively minor levels of injury, while priming tissues for injury during subsequent reperfusion.28,29 Studies in horses using low-flow ischemia indicate that equine tissues are susceptible to reperfusion injury after this type of ischemia.30,31,32 For example, studies of equine jejunum have shown that increased capillary permeability is associated with neutrophil infiltration during reperfusion.30 Although a direct link to xanthine oxidase has not been shown, equine small intestine expresses substantial levels of xanthine dehydrogenase, which is converted to xanthine oxidase during ischemia.33 Low-flow ischemia studies in equine colon have shown continued mucosal degeneration during reperfusion associated with marked neutrophil infiltration, despite the fact that equine colon does not express appreciable levels of xanthine oxidase. Alternative oxidant enzyme sources such as aldehyde oxidase have been offered as potential sources of reactive oxygen metabolites.34

Once the capacity of equine tissues to develop reperfusion injury was shown, additional studies were performed to determine whether reperfusion injury occurs after clinically applicable models of ischemia that simulate strangulating obstruction. For example, in one study assessing either arteriogenous or venous occlusion in equine jejunum, a small degree of reperfusion injury was documented after 3 hours of ischemia. However, the level of ischemic injury was nearly maximal after 3 hours, and the additional injury that developed during reperfusion was not sensitive to allopurinol, a xanthine oxidase inhibitor, or dimethyl sulfoxide, a reactive oxygen metabolite scavenger.34 The likely cause of reperfusion injury in this instance was initiation of epithelial injury during ischemia that could not be reversed during reperfusion.35 More recent studies in equine small intestine,38 and studies in equine colon,55 using ischemic models relevant to strangulating obstruction have failed to detect any level of reperfusion injury. Studies in laboratory animals on strangulating obstruction have also shown that this type of ischemic insult is less likely to develop into reperfusion injury.36,37

In a veterinary review of the pathogenesis of intestinal reperfusion injury in the horse, the concept of a therapeutic window wherein treatment of reperfusion injury would be beneficial was suggested.55 The basis of this concept is
That there are certain conditions under which ischemic injury is minimal, and that tissues are severely damaged during reperfusion. Thus, under conditions of low-flow ischemia, very little injury is demonstrated during 3 hours of ischemia, but remarkable injury occurs during 1 hour of reperfusion. However, a very narrow therapeutic window may exist under conditions of strangulating obstruction, where severe injury occurs rapidly during ischemia, leaving relatively little potential for further injury that can be potentially offset with treatments such as antioxidants during reperfusion.

Nonetheless, this does not mean that treatments directed against reperfusion injury have no potential place for treatment of horses with strangulating obstruction, particularly as these treatments become more effective. For example, multimodal therapies involving intravascular or intraluminal infusion of solutions containing antioxidants, intestinal nutrients, and vasodilators have proven very effective in vitro and in vivo, although these treatment modalities have been used predominantly in low-flow ischemia models. It is also becoming clear that the consequences of reperfusion injury are widespread and involve tissues other than the intestinal mucosa. For instance, low-flow ischemia models have demonstrated neutrophil infiltration into the seromuscular layers that very likely contributes to important complications such as adhesions and postoperative ileus. This neutrophil infiltration appears to be relevant to strangulating obstruction, because similar neutrophil infiltrates were noted in the resection margins of resected strangulated small intestine. Thus, although antioxidant-based therapies may be unable to reduce mucosal injury because of its rapid onset during ischemia, they may be able to reduce neutrophil infiltration in other layers of the intestine.

**DETERMINATION OF INTESTINAL VIABILITY**

**Clinical Assessment of Bowel Viability**

The viability of intestinal tissue is most commonly assessed by clinical observation—observing the color of the serosa and assessing the color of the mucosa, which may in some instances be observed prior to resection. For example, when a pelvic flexure enterotomy is performed in horses with large colon volvulus, the mucosa can be directly observed prior to making any decisions on recovering the horse or performing a resection. Changes in coloration are not uniform between the mucosa and the serosa, suggesting that much information can be gained by observing both of these layers of the intestine. For example, in one study on naturally occurring cases of large colon volvulus, the serosa was noted to turn from various shades of purple to pink in some instances as the colon was reperfused, whereas the mucosa consistently remained black. This probably relates to the metabolic demand of mucosa, which requires tremendous energy reserves to fuel the Na+/K+–ATPase mechanism that is responsible for driving mucosal transport function. Although there has been some concern about the utility of assessing mucosal color at the pelvic flexure, and about whether this accurately reflects the level of injury in the more proximal regions of the colon, recent studies suggest that injury is uniform throughout the strangled portion of the large colon.

Clinical determination of viability has the obvious advantage of being noninvasive and rapid to perform, but it has the disadvantage of being inaccurate for fully determining the level of injury. For example, in a study assessing the resection margins after small intestinal resection, it was noted that there was marked serosal inflammation at the proximal resection margin, a region where surgeons would have had the choice to resect additional intestine if needed. In other instances, when the resection margins are forced by anatomic considerations, surgeons can frequently discern substantial intestinal injury, but they have to decide whether the horse can survive if injured intestine is left in place. This is a particular problem with ileal resection and with large colon resection. Generally, if the intestine appears completely nonviable (on the basis of dark coloration, a dull appearance to the serosa, and an inability of the surgeon to rehydrate the surface of the intestine with lavage solutions), owners are advised that euthanasia is the most reasonable option.

However, bowel that appears nonviable sometimes does survive. For example, in a study of ponies subjected to small intestinal venous strangulation obstruction, in which assessment of viability was based on color, wall thickness, peristalsis, and palpable mesenteric arterial pulsation, clinical assessment was only 54% accurate in predicting viability. In particular, clinicians were misled by intramural hemorrhage and edema, which resulted in the faulty judgment of nonviable tissue in some instances. Ultimately, histopathology is the gold standard for determining viability, but when this service is unavailable because the situation is an emergency, any change in coloration during reperfusion, or evidence of bleeding from the vasculature during resection, may be used as evidence that there is some likelihood of survival. On the other hand, hemorrhage and edema within the tissues must be interpreted with caution, because some apparently devitalized bowel may survive.

**Ancillary Methods of Determining Intestinal Viability**

**Fluorescein Dye**

Fluorescein dye may be administered intravenously (6.6 to 15 mg/kg), after which it is rapidly distributed throughout the body, including the intestinal tract. Perfusion can be detected by illumination of the bowel with an ultraviolet light within 60 seconds of administration. Although there are distinct patterns of fluorescence in different segments of the intestinal tract, this technique has not gained wide clinical usage, most likely because of inconsistencies of the technique in enhancing accuracy of viability determination. In particular, a complete lack of fluorescence may be noted in clinical cases of ischemic small intestine that has subsequently been documented to survive. This may be caused by the degree of intestinal distention, or by the compromised systemic cardiovascular status, both of which are common problems in horses with colic. One way to overcome this problem is to carefully compare a segment of suspected ischemic intestine with adjacent normal-appearing intestine. A generalized lack of fluorescence over the entire region would indicate that the technique should not be used to make definitive decisions in that particular case, whereas fluorescence in adjacent normal intestine would at
least suggest that fluorescein is adequately perfusing the intestinal segment of interest.

In a study comparing the accuracy of fluorescein administration with clinical judgment and Doppler ultrasound in determining viability in strangulated small intestine, fluorescein administration uniformly predicted viability correctly in cases of ischemic strangulating obstruction, but it was very poor in predicting viability in cases of hemorrhagic strangulating obstruction. The latter may result from reduction in fluorescence as a result of the presence of hemorrhage and edema, leading to an overly pessimistic interpretation of viability. As opposed to viability of the small intestine, large intestinal viability may be more adequately assessed using the fluorescein technique. However, great caution has to be exercised when interpreting the results. For example, a patchy pattern of fluorescence is not necessarily an indication of nonviability, but if the fluorescent patches constitute a minor portion of the colonic surface, nonviability is likely. On the other hand, a diffuse granular pattern of fluorescence is usually indicative of tissue that is viable.

Surface Oximetry
An alternative technique for assessing viability is the measurement of intestinal serosal surface oximetry, which is an indirect measure of tissue oxygenation. As with other techniques for assessment of viability, other circulatory factors have to be taken into consideration, including the overall cardiovascular status of the patient. A contact probe may be placed on the intestinal serosal surface, which measures surface oxygen partial pressure (PSO2). Normal PSO2 values for the jejunum, ileum, and pelvic flexure of healthy anesthetized horses are 71 ± 20, 61 ± 8, and 55 ± 13 mm Hg, respectively. This information has been used to assess the viability of the colon after correction of large colon volvulus. Overall, the accuracy of surface oximetry in predicting colonic viability was 88%, using a set point of 20 mm Hg surface oxygen tension.

Additional analyses revealed that a horse with a PSO2 value of 20 mm Hg or less was 7.4 times more likely to die than a horse with a higher PSO2 value. However, PSO2 values have to be interpreted cautiously. In particular, the sensitivity of the technique was only 53% (calculated as the number of horses with an oximetry value of 20 mm Hg or less divided by the total number of horses that died), whereas the specificity was 100% (calculated as the number of horses that survived with an oximetry value of greater than 20 mm Hg divided by the total number of horses that survived). Thus, the technique is very useful for detecting horses that will survive, but predicting nonsurvival in horses with low PSO2 values is very inaccurate. The other major disadvantage of this technique is that it measures surface oxygen tension in focal areas of application and cannot be used to give an indication as to the viability of an entire region of intestine.

Doppler Ultrasonography
Doppler ultrasonography has been used to discern viability on the basis of detection of flow through the microvasculature. A study described earlier (see “Fluorescein Dye”) compared Doppler ultrasonography to use of clinical judgment and intravenous fluorescein. Doppler ultrasonography was shown to be the most accurate technique for detecting viability in poststrangulated small intestine (accuracy values of 88%, 53%, and 53% for Doppler, clinical judgment, and fluorescein, respectively). The increased accuracy for Doppler ultrasonography was particularly evident in horses with experimental small intestinal hemorrhagic strangulating obstruction, in which viability was far more accurately determined with Doppler than other techniques. However, clinical judgment and fluorescein were slightly more accurate than Doppler for determining viability in experimental small intestinal ischemic strangulating obstruction.

Luminal Pressure
Increased intraluminal pressure is correlated with nonsurvival in horses with small intestinal obstruction and is probably related to the degree of mucosal injury generated by compression of the intramural blood supply. For example, in one study, survivors and nonsurvivors with small intestinal lesions had mean pressures of 6 cm H2O and 15 cm H2O, respectively. Although 15 cm H2O is lower than the level that induced epithelial sloughing in experimental studies, the duration of the pressure changes may be far greater in horses with naturally occurring lesions. Thus, a single pressure measurement may not be predictive of the severity of mucosal lesions without factoring in the duration of the disease. In horses with large colon volvulus, an increasing pressure is also correlated with nonsurvival. Using a set value of 38 cm H2O, survivors were separated from nonsurvivors (with a sensitivity and specificity of 89% and 91%, respectively), indicating that this test is highly accurate for predicting survival of horses with large colon volvulus.

Histopathology
The gross and histopathologic appearances of tissues were carefully evaluated in horses with naturally occurring large colon volvulus, and a number of parameters described in this study were subsequently used to predict survival in horses with large colon volvulus. Biopsies were taken from the pelvic flexure (previously shown to accurately reflect mucosal changes along the length of the colon) and histologically examined. The study used biopsies fixed in 10% neutral buffered formalin or frozen in liquid nitrogen. Although the latter technique resulted in some loss of tissue detail, the authors did not feel that this impaired the use of these biopsies for determination of survival. Furthermore, frozen tissues would be required if this technique were to be used intraoperatively. However, postoperative evaluation of formalin-fixed specimens may provide useful information on horses that have survived surgery but that are experiencing major problems in the postoperative period. Owners may elect euthanasia in some cases, if the lack of postoperative progress is reinforced by histopathology that suggests nonviability of bowel remaining in the horse.

Specific parameters recorded on histologic evaluation in these studies included the percentage loss of surface epithelium, the percentage loss of glandular epithelium, and the
width of the crypts and of the interstitial space between the crypts. The latter measurements were expressed as an interstitium-to-crypt width (I:C) ratio. Normal values for this ratio are 1 or less. Additional scored parameters included the degree of hemorrhage and the degree of edema (0, no edema or hemorrhage; 4, marked edema or hemorrhage), but these scores were not used in overall survival analyses. Colonic tissue was considered to be nonviable when the I:C ratio was greater than 3 and the loss of glandular epithelium was greater than 50%. Using these parameters, survival was correctly predicted in 94% of horses.

REFERENCES
The terminal ileum forms a papilla that projects into the cecum. The ileal orifice is located in the center of the papilla, surrounded by the cecal musculature, an annular fold of mucous membrane, and a venous network. The muscle of the ileocecal papilla is composed of three layers: an inner circular layer, a central longitudinal muscle layer from the ileum, and an outer layer formed from the circular muscle of the cecum and arranged into two semicircular lips. The papilla lacks a true sphincter, although the lumen of the ileum appears reduced at the ileocecal junction. The proposal that the venous network and annular fold contribute to the sphincter mechanism is rendered less tenable by the observation that the veins are most engorged when the ileum is discharging its contents into the cecum. A functional sphincter does exist and appears to contract in synchrony with contractions of the cecal base. Endoscopic studies of the cecal base of the horse have demonstrated that the ileal papilla is very prominent and that it becomes more prominent when the cecum is active.

**Digestive Anatomy**

Digestion and absorption of nutrients take place predominantly in the upper half of the small intestine. Unique to the small intestine in adults are finger-like projections of the epithelial surface called villi, and each villus is surrounded by approximately six to nine crypts of Lieberkühn. The equine small intestine lacks mucosal folds and/or plicae circulares. Columnar absorptive cells or enterocytes constitute most of the small intestinal epithelial cells (about 90%), and the remainder are mucous (goblet) cells, enteroendocrine cells, Paneth cells, and undifferentiated columnar cells. After at least two divisions within the crypt, the columnar cells migrate onto the villus as mature absorptive cells, and they are finally extruded at the villous tip, usually with a turnover time of 2 to 3 days. Cells in the upper third of the villi are capable of surface digestion of nutrients and active transport of digestion products.

The apical surface of a mature enterocyte is arranged into microvilli that form a brush border membrane. Enterocytes are connected to each other by tight junctions that restrict...
CHAPTER 35

Small Intestine
David E. Freeman

ANATOMY

The equine small intestine varies from 10 to 30 m in length, with an average length of approximately 25 m. The duodenum, with an average length of 1 m, extends from the pylorus to the right of the midline, along the right dorsal abdomen, to a point caudal to the root of the mesentry. The duodenal ampulla and cranial flexure bend the first segment into the S-shaped sigmoid ansa. The major duodenal papilla (opening of the bile and pancreatic duct) and the minor duodenal papilla (opening of the accessory pancreatic duct) are located in the cranial flexure. Caudal to the right kidney, the duodenum is attached to the transverse colon by the duodenocolic fold. It forms the duodenocolic flexure at its junction with the jejunum.

The jejunum measures 17 to 28 m in adult horses and is situated mainly in the left dorsal quadrant of the abdomen, between loops of small colon. The arterial supply from the cranial mesenteric artery is carried in arcades in the long mesojejenum (40 to 60 cm), which allows the jejunum much mobility. Each vascular arcade is composed of a major jejunal vessel, an arcuate vessel that forms a loop with the next jejunal vessel, and several vasa recta that pass from the arcuate vessels to the intestinal wall. Veins run parallel to the arterial supply and enter the portal vein to provide venous drainage. The ileum is 0.7 m long, and its length is marked by the distinct ileocecal fold that attaches its antimesenteric side to the dorsal band of the cecum. The arterial supply is provided by the ileocecal artery, a branch from the cranial mesenteric artery that travels along the ileum to anastomose of digestion products.

the transmucosal flux of large molecules, although they are permeable to water and many low-molecular-weight substances.\textsuperscript{12,13} (Fig. 35-1). The intercellular space and the tight junctional complexes form the paracellular channel,\textsuperscript{14} and the intercellular space expands during water absorption.\textsuperscript{13} Enzymes that complete digestion of carbohydrates (disaccharidases) and proteins (peptidases) as well as various specific transport systems for absorbing digestive end products are located within the microvilli (Fig. 35-2).

**PHYSIOLOGY**

**Intraluminal Digestion**

Dietary carbohydrates, fats, and proteins are broken down by pancreatic enzymes in the small intestine, and their breakdown products are hydrolyzed further by brush border enzymes.\textsuperscript{8,15} Hydrogen ion in the duodenum causes the release of secretin from S-cells, which stimulates the pancreas and liver to secrete HCO\textsubscript{3}\textsuperscript{−} and water.\textsuperscript{11,16} Bicarbonate neutralizes H\textsuperscript{+} ions in the proximal small intestine and thereby prevents acid-pepsin damage to duodenal mucosa, provides a functional pH\textsuperscript{1} for pancreatic and brush border enzymes, and increases solubility of bile acids and fatty acids.\textsuperscript{7} Protein and fat in the duodenum stimulate the release of cholecystokinin (CCK) from I-cells, and CCK causes the pancreas to secrete enzymes for the digestion of carbohydrates (amylase), fat (lipase), and protein (trypsin, chymotrypsin, carboxypeptidase, and elastase), as well as cofactors (colipase) that aid in enzymatic digestion.\textsuperscript{7,16}

Trypsinogen, the precursor form (or zymogen) of trypsin, must reach the small intestine to be activated by the brush border enzyme enteropeptidase.\textsuperscript{7} Other enzymes that are secreted as zymogens can be activated only by trypsin. Resting pancreatic secretions in the horse are profuse, apparently continuous (10 to 12 L/100 kg body weight per day), and increased rapidly by eating.\textsuperscript{17} The concentration of HCO\textsubscript{3}\textsuperscript{−} is low, so that Cl\textsuperscript{−} remains the predominant inorganic anion in the horse's pancreatic secretion at all rates of flow.\textsuperscript{17,18} Therefore, the pancreatic secretion may provide a source of anion (Cl\textsuperscript{−}) for exchange with HCO\textsubscript{3}\textsuperscript{−} in the terminal ileum to buffer products of fermentation in the cecum and colon.\textsuperscript{17,18} Although content and output of pancreatic enzymes is small in the horse compared with other animals,\textsuperscript{17} digestion and absorption appear to be as efficient.\textsuperscript{19}

In the liver, cholic acid and chenodeoxycholic acid\textsuperscript{20} combine with glycine and taurine to form conjugated bile salts. Lipolysis in the small intestine requires emulsification of fat by bile salts.\textsuperscript{7} Micelles form when the bile salts reach the critical micellar concentration (CMC) in the small intestine to aid in fat absorption (see "Fat Absorption," p. 403). Approximately 94% of bile salts are reabsorbed by the small intestinal mucosa, they pass to the liver, and they are then resecreted, a process called enterohepatic circulation of bile.\textsuperscript{7,20} Active transport by a Na\textsuperscript{+}-dependent process in the ileum and by passive absorption in the jejunum combine to reclaim intraluminal bile. Secondary bile salts are produced from bacterial deconjugation and dehydroxylation of bile salts that are not absorbed in the small intestine and enter the colon. These secondary bile salts are lost in feces and are replaced continually by liver cells.\textsuperscript{7,20}

**Absorption of Ions and Water**

Most water absorption takes place in the distal third of the small intestine, but the bulk of intestinal water is absorbed by the large intestine.\textsuperscript{18} However, Na\textsuperscript{+} and water absorption in the small intestine is important in absorption of nutrients and other ions.
The routes for transepithelial movement of ions and water (see Fig. 35-1) are through the cell (transcellular) and through the paracellular space (extracellular). Transcellular movement of Na+ involves entry from the lumen into the cell, down an electrochemical gradient. However, exit of Na+ from the cell is against an electrochemical gradient and is therefore an active process that requires energy from the Na+ pump (Na+/K+–ATPase), located along the basal and lateral membranes. The active transport of Na+ across the cell creates a transmucosal electrical potential difference.

The electrochemical gradient for Na+ across the apical membrane has sufficient potential energy to move Cl− into the cell against its electrical gradient. The cotransporter of both ions is brought about by a carrier mechanism on the luminal membrane that is specific for Na+ and Cl− (see Fig. 35-1). The net movement of Cl− by this mechanism is called secondary active transport. The Na+ gradient also energizes uptake of hexoses (glucose), amino acids, and most B vitamins against their chemical gradients into the cell.

Water transport is passive, closely coupled to solute movement, and is primarily paracellular (see Fig. 35-1). As absorbed Na+ is pumped across the basolateral membrane, it creates an osmotic gradient that draws water into the intercellular space. As water accumulates in this space, it increases the hydrostatic pressure, and this pressure forces the water across the basolateral membrane toward the capillary. Although the tight junction restricts backflow of water across the basolateral membrane, paracellular permeability and back-leak through this route is high in the jejunum. Therefore, Starling forces have a considerable influence on ion and fluid transport in the proximal bowel, just as in the proximal tubule of the kidney.

Net water movement from lumen to plasma through the paracellular route will "drag" permeant ions and low-molecular-weight substances with it (sugars, amino acids, Ca2+, and Mg2+), and this mechanism is called solvent drag, or convection. Fluid absorbed by the epithelium moves into the central lacteal of the villus, from which it moves into the deeper lymphatics. There is little proof that the intestinal villus has a countercurrent multiplier that could enhance water and solute absorption, at least in the dog.

Carbohydrate Absorption

Several brush border oligosaccharidases and disaccharidases hydrolyze initial products of starch digestion by amylase to produce monosaccharides, such as D-glucose, D-fructose, and D-galactose (see Fig. 35-2). In horses on a grass-based diet, sucrase activity in the proximal small intestine is comparable to that reported in other nonruminants. Malate distribution is constant along the equine small intestine, and its activity is higher than in other species. Lactase activity is higher in equine jejunum than in other parts of the small intestine, and it does decrease with maturity. Lactose and D-glucose are transported across the enterocyte membrane by a high-affinity, low-capacity, Na+-dependent cotransporter type 1 isoform, SGLT1 (see Fig. 35-1). The major site of D-glucose uptake by the SGLT1 transporter in horses is the duodenum, followed by the jejunum and then the ileum. Fructose moves from the lumen into the cell by facilitated diffusion through the GLUT5 transport system, which is a high-capacity, low-affinity, Na+-independent transporter in the equine small intestine. The monosaccharides diffuse down their concentration gradient in the absorptive cell into plasma through a GLUT2 passive transport mechanism and then enter the portal venous system.

Protein Absorption

Small neutral peptides yielded by pancreatic peptidases are broken down by brush border oligopeptidases (see Fig. 35-2) into dipeptides and tripeptides or amino acids. In the enterocyte, the peptides are hydrolyzed by cytoplasmic oligopeptidases into their constituent amino acids, which move passively into portal blood down a concentration gradient. Consequently, many dipeptides and tripeptides are transported into the cell, but mostly free amino acids enter portal circulation.

The intestine has several distinct amino acid transport systems, with varying degrees of specificity for amino acids and differences in Na+ dependence. The transport systems for small peptides are H+ dependent. Circulating and intraluminal amino acids can also be used by the intestinal epithelial cells as energy sources.

Fat Absorption

Long- and medium-chain triglycerides are split into constituent fatty acids and monoglycerides by pancreatic lipase interacting with colipase. The resulting long-chain fatty acids and 2-monoglycerides, as well as fat-soluble vitamins and cholesterol, must combine with bile acids to form a water-soluble mixed micelle. This micellar solubilization facilitates movement of lipids through the unstirred water layer to the brush border, where the micelles release their components for absorption. Because of their fat solubility, the released long-chain fatty acids and 2-monoglycerides can traverse the membrane down a concentration gradient. Fatty acids and 2-monoglycerides in the mucosal cell undergo reesterification and formation of chylomicrons, and chylomicrons are taken up by the lymphatics.

Absorption of Iron, Calcium, and Magnesium

Iron transport is closely regulated to meet the body's needs. Some absorbed iron combines with an intracellular protein, called apoferritin, to form an iron complex called ferritin. If no binding protein is available, absorbed ferrous iron is transported out of the cell through transferrin receptors and is released to the circulation. If iron stores are low in the body, crypt cells migrating to the villus tip are low in apoferritin but high in basolateral transferrin receptor. As ferrous iron enters the cell from the lumen, it is not bound and is therefore free to enter the circulation to replenish iron stores. On the other hand, with a large iron store in the body, the crypt cell reaches the villus tip as a mature cell high in apoferritin. As ferrous iron enters the cell from the lumen, it is therefore bound and stored, and this bound iron is lost as the cell exfoliates at the end of its life span.

Lumen-to-plasma flux of calcium is highest in the duodenum. A high concentration of dietary magnesium can decrease calcium absorption through competition for the
calcium transport site. Absorbed calcium enters the cell down an electrochemical gradient and is transported through the cytoplasm complexed with a specific calcium-binding protein. This protein is regulated by the biologically active form of vitamin D, 1,25-dihydroxycholecalciferol. Extrusion from the cell is against an electrochemical gradient through the Ca\(^{2+}\)-ATPase.

Magnesium absorption is of interest because magnesium sulfate is used as a laxative in horses, and the extent of absorption could alter its laxative effects and the risk for magnesium toxicity. Mean magnesium absorption is approximately 40% to 70% in growing foals and mature ponies, and the absorption occurs primarily in the proximal small intestine.

**Intestinal Secretion**

Crypts of Lieberkuhn are located over the mucosal surface of the small intestine and secrete an almost pure extracellular fluid that maintains chyme in a fluid state, delivers secretory IgAs, and flushes crypts of noxious and infectious agents. Intestinal water and electrolyte secretion is determined primarily by Cl\(^{-}\} secretion by crypt cells, with movement of Na\(^{+}\) and water following. Intestinal secretion is under a degree of neural and eicosanoid tone.

Protective mucus is secreted by mucous cells located extensively over the surface of the intestinal mucosa, and by Brunner’s glands, which are located in the first 9.6 m of the equine duodenum. The function of mucus from Brunner’s glands is to protect the duodenal wall from digestion by gastric secretions.

**Motility**

Small intestine has an outer longitudinal smooth muscle and an inner circular muscle layer, and the latter is divided into a thick outer lamella and a thin inner lamella. Rhythmic segmentation in circular smooth muscle and synchronous shortening of the longitudinal muscle causes aboral transit during peristalsis. The interstitial cells of Cajal are thought to act as pacemakers for the generation of electrical slow waves that propagate into the longitudinal muscle layer.

Two basic components of myoelectrical activity of gastrointestinal smooth muscle are the slow wave (basic electrical rhythm, or electrical control activity) and the action potential (“spike potential”). Slow waves are phasic oscillations of the smooth muscle resting membrane potential that are considered responsible for the rhythmicity and polarity of intestinal contractions. In the pony, as in other animals, slow-wave frequency is greater in the duodenum and decreases toward the ileum. This determines the direction and propagation rates of associated motility.

An action potential is generated if something lowers the threshold of the smooth muscle cells, allowing a slow-wave oscillation to reach a threshold and cause a rapid depolarization that triggers intestinal contractions. Mechanical (stretch), neural, and hormonal stimuli determine if that threshold will be reached. Action potentials do not necessarily occur with every slow wave, but slow-wave frequency determines the maximal frequency of action potentials.

These wave forms produce a distinct pattern of myoelectrical activity called the migrating motor complex (MMC). Three phases of activity are recognized. Phase I, or no spiking activity (NSA), has slow waves only and no action potentials (Fig. 35-3). Phase II, or intermittent or irregular spiking activity (ISA), has intermittent action potentials on some slow waves. Phase III, or regular spiking activity (RSA), is evident as an action potential for every slow wave and thus is associated with intense, sustained contractions. The MMC is always present during an “interdigestive state” (time between meals when stomach and small intestines are essentially empty) and plays an important role in reducing bacterial colonization in the small intestine. Phases II and III are associated with intestinal contractions, and most of an ingested meal is moved through the small intestine by phase II activity.

**Control of Motility**

Control of motor events in the small intestine involves myogenic, neural, and hormonal mechanisms. Neural control involves the vagus nerve and components of the sympathetic nervous system, as well as an intrinsic system called the enteric nervous system. The enteric nervous system consists of ganglia in the myenteric (Auerbach’s) plexus and the submucosal (Meissner’s) plexus, and it mediates reflex behavior independent of input from the brain or spinal cord. Myenteric neurons are the main source of innervation of longitudinal muscle and the outer lamella of circular muscle. Submucosal neurons innervate the inner lamella of circular muscle. Hormonal control of motility involves neurotransmitters and other neural agents that act on intestinal smooth muscle. Motilin, a peptide produced by endocrine cells in the mucosa of the proximal small intestine, is released during fasting, and it regulates the interdigestive migrating motor complex. A coordinated release

---

**Figure 35-3.** Myoelectrical activity of the duodenum of a clinically normal horse, demonstrating all components of the migrating motor complex (phases I through III). The slow wave frequency is about 14 per minute in all segments. (Modified from Merritt AM, Burrow JA, Hartless CS: Effect of xylazine, detomidine, and a combination of xylazine and butorphanol on equine duodenal motility, Am J Vet Res 1998;59:619-623, with permission.)
of excitatory and inhibitory transmitters coordinates the peristaltic reflex responsible for propulsive activity.10

Motility of the Ileum
The migrating action potential complex (MAPC) can be recorded in the pony ileum as intense spike bursts of short duration that propagate rapidly aborally, but they are absent in the pony jejunum. In the ileum of mature ponies, all phases of the MMC can be recorded, but irregular spiking activity (phase II) predominates during the interdigestive period (the period between feeding). Withholding food for 24 hours decreases the frequency of ileal MAPC, but it has no effect on mean slow-wave frequency, MMC phase distribution, MMC phase duration, MAPC conduction velocity, or conduction velocity of spike bursts in RSA. Differences between the ileum and the jejunum in ponies might be related to the unique position of the ileum at the junction of the small and large intestines. The MAPC is seen directly before retrograde cecal myoelectric activity 73% of the time, indicating a possible myoelectric coupling of the ileum and cecum, and it may be responsible for transit of digesta from the ileum to the cecum. Also, ileal contents are discharged into the cecum at times when the cecum is inactive. Ileal and cecal filling appear to be more important in regulating ileocecal motility events in ponies than stimuli associated with feeding. Local stimulation of chemoreceptors could be important in the regulation of ileal motility in the horse and humans. Also, the human ileum, and possibly the equine ileum, act as reservoirs, discharging contents into the cecum in response to intraluminal stimuli. At neutral pH, tonic activity of the human ileum, but not of the jejunum, is increased by intraluminal short-chain fatty acids, whereas bile acids and lipids can induce ileal relaxation. In the pony, serotonin and luminal fatty acids increase ileal peristalsis. The response to luminal acidification could stimulate ileal emptying of refluxed bacteria and cecal contents and could thereby augment the sphincter function of the ileal papilla. Although tone of the ileal papilla increases during contractions of the cecal base in horses, some cecal contents do reflux into the ileum. Sympathetic relaxation of ileal smooth muscle is mediated mainly by activation of β-antical receptor subtypes, and increased ileal sphincter tone is mediated through α1 receptors. Whereas epinephrine decreases ileal and cecal activity, it increases ileal sphincter tone through α1 receptors.

Altered Motility
Xylazine, atropine, meperidine, butorphanol, and pentazocine can increase the mean duration of MMC in pony distal jejunum, whereas flunixin meglumine, dipyrone, metoclopramide, and panthenol have no effect. Xylazine and butorphanol (as separate treatments) reset the duodenal MMC in the horse, but without serious disruption of proximal gastrointestinal tract motility. However, routine doses of xylazine, detomidine, or a xylazine and butorphanol combination significantly reduce pressure peaks in the duodenum. Common anesthetic regimens decrease myoelectric activity in horse ileum for up to 150 minutes after induction. After small intestinal resection and anastomosis in the dog, the aboral progression of the MMC stops at the anastomotic site, and alternate pacemakers initiate regular spiking activity distal to the anastomosis. In the distal segment, the number of phases are reduced, disrupted, and delayed, and transit time is delayed also. Therefore, timing of the MMC appears to depend on bowel continuity and integrity of intrinsic innervation.

Nonstrangulating obstruction of distal jejunum causes immediate continuous spiking activity proximal to the obstruction. This response is not associated with fluid distention and does not cause signs of colic until accompanied by increased intraluminal pressures. Occlusion of blood supply to the pony ileum decreases motility in the ischemic bowel, increases motility in the more proximal segment, and has no effect on the distal segment. A low dose of endotoxin and intravenous infusion of prostaglandin E2 alter regular spiking activity in pony jejunum, which suggests a role for endotoxin in postoperative ileus. Nitric oxide also appears to act as an inhibitory neurotransmitter to circular smooth muscle of equine jejunum and could be released from invading macrophages in distended or inflamed small intestine.

PATHOPHYSIOLOGY
Small Intestinal Distention
Intestinal obstruction causes prestenotic distention with gas, fluid, and ingesta that can compress intestinal veins. Most of the resulting increase in venous pressure is transmitted to the capillary beds, and consequently capillary pressure increases. The intestinal wall becomes thicker because of edema induced by increased capillary filtration. The resulting filtration of fluid from capillaries into the interstitium is opposed by changes in Starling forces that attempt to maintain the tissues in a more dehydrated state. As these compensatory mechanisms become overwhelmed, continued capillary filtration increases tissue edema and movement of fluid in large volumes into the intestinal lumen, producing a net secretion of fluid into the intestine. An experimentally induced intraluminal pressure of 25 cm H2O (18.4 mm Hg) for 120 minutes in equine jejunum causes shortening of villi, loss of mesothelial cells, neutrophil infiltration, edema in the seromuscular layer, and a decreased number of perfused vessels in the seromuscular layer as well as in the mucosa. Decompression of distended equine jejunum may not prevent progression of the morphologic lesions, but it permits partial recovery of vascular density. Serosal edema and infiltration with erythrocytes and leukocytes increases significantly after distended equine jejunum is decompressed, and to a greater extent than in reperfused ischemic jejunum. These serosal changes could contribute to complications in distended bowel proximal to an obstructive lesion, such as serosal adhesions.
**Small Intestinal Ischemia**

Venous occlusion occurs rapidly when thin-walled veins are compressed by the edges of a hernial ring or by twisting of mesentery. The increased venous pressure causes edema and net secretion of fluid, as well as a myogenic response (the Bayliss effect) that protects the tissues from an increased vascular load. This effect increases vascular resistance to arterial inflow, which combines with the decreased pressure gradient from artery to vein to reduce blood flow. This response, coupled with arterial compression caused by displacement, eventually blocks arterial inflow and causes ischemia. Erythrocytes extravasate through altered capillaries and cause the characteristic intramural hemorrhage, which is known as hemorrhagic infarction. Equine jejunum strangulated in a closed space develops tissue changes more slowly than in the open abdomen model and into a meshlike capillary network that descends along the arteriole that spirals to the villus tip and then “fountains” into a meshlike capillary network that descends along the arteriole that spirals to the villus tip and then “fountains” equine jejunal villus is supplied by an eccentrically placed gradient from artery to vein to reduce blood flow. This arterial inflow, which combines with the decreased pressure gradient from artery to vein to reduce blood flow. This effect increases vascular resistance to arterial inflow, which combines with the decreased pressure gradient from artery to vein to reduce blood flow. This response, coupled with arterial compression caused by displacement, eventually blocks arterial inflow and causes ischemia. Erythrocytes extravasate through altered capillaries and cause the characteristic intramural hemorrhage, which is known as hemorrhagic infarction. Equine jejunum strangulated in a closed space develops tissue changes more slowly than in the open abdomen model and therefore might be more representative of a naturally acquired strangulation.

Because ischemia reduces oxygen delivery to the metabolically active mucosa, morphologic changes develop that can be graded in severity from grade I (development of a subepithelial space, called Gruenhagen’s space, and slight epithelial lifting at the villus tip) to grade V (complete loss of the villus architecture, with severe mucosal hemorrhage and loss of the lamina propria). The intermediate grades represent a progressive loss of the epithelial layer, starting at the villus tip. As a consequence of this mucosal damage, the important epithelial barrier is lost, and endotoxin can leak across to the peritoneum and be absorbed into the circulation, causing endotoxemia.

In a pattern similar to that seen in other animals, the equine jejunal villus is supplied by an eccentrically placed arteriole that spirals to the villus tip and then “fountains” into a meshlike capillary network that descends along the periphery of the villus to drain into one to three venules. This creates a countercurrent mechanism that allows capillaries near the villus base to “shunt” oxygen from the tip, rendering it more sensitive to hypoxia relative to the rest of the villus. However, this does not appear to be the only or even the most important explanation for the sensitivity of villus cells to anoxia, because anoxic injury to equine jejunum in vitro causes the same progression of epithelial damage. Most likely, cells on the villus tip are the first to succumb to anoxia because they are closer to the end of their life span.

Intestinal smooth muscle is more resistant to hypoxia than mucosa, and crypt cells are more resistant than villus cells—factors that can play a part in recovery from an ischemic insult. In the early stages of mucosal repair, viable cells migrate from the crypts to cover the exposed villus stroma, whereas damaged cells are removed by detachment and phagocytosis. This repair process is called restitution, and it explains how equine jejunum subjected to a grade IV injury becomes covered with stunted villi, lined with cuboidal epithelium, within 12 hours. Normal architecture of the mucosal lining is restored rapidly from this point. Although the intestinal wall can recover from venous strangulating obstruction, mesentery subjected to hemorrhage and edema is prone to fibrosis, shortening and adhesions. Serosal edema and infiltration with erythrocytes and leukocytes increase significantly after ischemia/reperfusion in equine jejunum to an extent that could predispose to adhesions.

Other factors that can contribute to the mucosal injury in ischemic intestine are those that alter capillary permeability, such as endotoxin, reactive oxygen metabolites, histamine, and activated neutrophils (for an in-depth discussion of intestinal injury, see Chapter 34).

**DIAGNOSIS OF SMALL INTESTINAL OBSTRUCTION**

Preoperative prediction of a small intestinal versus large intestinal lesion is highly successful, but identification of the specific intestinal lesion is rarely possible, except for strangulation in an external hernia. Clinical findings vary enormously, and small intestinal diseases that require surgery are difficult to distinguish from those that can respond to medical treatment, such as duodenitis–proximal jejunitis and ileal impaction.

Horses with small intestinal strangulating obstruction usually exhibit signs of acute, severe abdominal pain and hypoperfusion, have an elevated heart rate and packed cell volume, and develop acidosis. The signs of distal obstructions develop more slowly, and the electrolyte imbalances and cardiovascular responses are less severe initially than with proximal lesions. Horses with proximal jejunitis may have severe abdominal pain initially; this progresses to depression and less pain than in horses with ileal impaction or strangulating obstruction. After gastric decompression, horses with proximal enteritis usually improve in overall attitude and their heart rate decreases, whereas horses with mechanical obstructions do not improve.

Distended loops of small intestine on rectal palpation indicate small intestinal obstruction from any cause. In studies on horses with small intestinal strangulation, distended loops were palpated in 50% to 98% of horses on palpation. In some horses with small intestinal strangulation, a large colon abnormality can be found on palpation per rectum that may not be evident at surgery. Many severely dehydrated horses with small intestinal diseases develop a “vacuum-packed” large colon, evident on rectal palpation as dehydrated colon contents contained within prominent colon haustra. These should not be mistaken for large colon impactions but might be considered as highly suggestive of small intestinal strangulation. The degree of intestinal distention is very variable, with severe distention more likely to be associated with a strangulating lesion than with ileal impaction or proximal enteritis. The amount of gastric reflux varies from none in the early stages of a lesion in the distal part of the small intestine, to several liters with a longstanding lesion or a lesion in the proximal part of the small intestine. Borborygmi are usually diminished or absent in all small intestinal diseases.

Abdominal distention is negligible to moderate in adult horses with small intestinal obstruction but can be pronounced in foals. Abdominal pain can be difficult to assess in foals with small intestinal strangulation because they can alternate between periods of violent colic and periods of depression. The latter can be interpreted erroneously as evidence of improvement. Inability to perform a rectal pal-
Peritoneal Fluid Analysis

Analysis of peritoneal fluid is important, but abdominocentesis is not necessary if other clinical findings indicate the need for surgery. Although the complications of enterocentesis are rare, peritonitis and abdominal wall cellulitis may develop after puncture of distended bowel. The risk of enterocentesis is greater in foals than in adult horses, although ultrasonography can identify fluid pockets to be sampled and also gives an impression of the volume and solid contents of the fluid. Peritoneal fluid can prolapse through the puncture site in a foal if a needle of 18 gauge or larger is used.

The nucleated cell count in peritoneal fluid of normal adult horses ranges from 5000 to 10,000 cells per microliter, but more than 1500 nucleated cells per microliter should be considered elevated in foals. Peritoneal fluid protein concentration is within the same range in foals as adults (0.3 to 1.8 g/dL). Peritoneal fluid usually becomes serosanguineous with a strangulating lesion, but this is not a consistent finding, especially early in the disease. Accidental blood contamination does not appear to significantly affect nucleated cell count and total protein concentration in a peritoneal fluid sample. Strangulated bowel in an inguinal hernia or intussusception is less likely to alter the peritoneal fluid than an intra-abdominal lesion but can produce serosanguineous fluid with elevated nucleated cell count and total protein. Small intestinal rupture or perforation will produce changes in peritoneal fluid suggestive of digesta contamination, such as cloudy or green discoloration, increased protein and cell count, and intracellular bacteria; however, normal cell counts and protein can also be recorded and plant material may not be evident.

Peritoneal fluid from horses with proximal enteritis is rarely serosanguineous, and nucleated cell count and total protein concentration increase to a lesser extent than with a strangulating obstruction. Therefore, peritoneal fluid is of some value in distinguishing between these diseases. Total protein can be elevated and eosinophils found in peritoneal fluid from horses with focal eosinophilic enteritis, a cause of small intestinal obstruction in horses. Peritoneal and serum phosphate levels can be used to predict major intestinal injury, although the ranges in horses with surgical and nonsurgical colic can have considerable overlap. (For an in-depth discussion of diagnostic approaches to the horse with colic, see Chapter 33.)

Gastrointestinal Tract Imaging

Ultrasonography is invaluable for examining horses with small intestinal obstruction. Liberal application of alcohol and gel to the horse’s hair coat are sufficient to improve acoustic coupling in most horses without clipping, but clipping of long hair coats can improve image quality. Most abnormalities gravitate to the ventral abdomen, where they are accessible for ultrasonography. A lower-frequency ultrasound transducer should be used (2 to 3.5 MHz) to penetrate deeper into the abdomen (approximately 24 cm) and higher-frequency transducers (5.0 or 7.5 MHz) can improve image detail in foals or superficial structures.

Small intestinal strangulating obstruction, peritonitis, peritoneal effusion, bowel rupture, intussusception, inguinal hernia, diaphragmatic hernia, choledochoptosis, abdominal neoplasia, abdominal abscess, and ascarid impactions can be detected by ultrasonography. Transabdominal ultrasonographic findings of small intestine that is edematous (wall thickness greater than 3 mm), distended, and amotile strongly suggest strangulating obstruction (see Figs. 33-1 and 33-2). As obstructed small intestine fills with fluid, its contents become more hypoechoic. The five ultrasonographic layers of the intestinal wall are lost in strangulated segments. Ultrasonography may be helpful in assessing gastric distention and in determining the efficacy of gastric decompression. The stomach can be located on the left side of the abdomen between the 11th and 13th intercostal spaces, at the level of the shoulder, dorsal to the splenic hilus and its large splenic vein. The greater curvature of the stomach is seen as a bright gas echo that curves toward the skin surface, deep to the spleen. Distention of the stomach can displace the spleen caudally or obscure it.

Regardless of the motility status, abdominal ultrasonography can provide a sensitivity of 98%, a specificity of 84%, a positive predictive value of 62%, and a negative predictive value of 99% for small intestinal strangulation obstruction from a variety of lesions. Under the same conditions, palpation per rectum can provide a sensitivity of 50% for small intestinal strangulation obstruction, which means that it is considerably inferior to ultrasonography in finding a small intestinal abnormality when one does exist. In horses with small intestine strangulated in the epiploic foramen, ultrasonography could accurately detect small intestinal distention in 94% to 100% of horses, compared with 74% to 78% for palpation per rectum. With this lesion, distended or edematous small intestine is found more often in the ventral right paralumbar fossa, caudal ventral abdomen, and middle right paralumbar fossa. For strangulating lipomas, similar intestinal changes are found more often in the caudal ventral abdomen, middle ventral abdomen, and ventral right paralumbar fossa than in other regions (see Chapter 33).

Abdominal radiography is useful in the foal with gastrointestinal obstruction, necrotizing enterocolitis, enteritis, impaction, displacement, intussusception, ruptured viscus, congenital anomalies, and inguinal hernia, and in the adult horse and foal with diaphragmatic hernia. In foals, radiographs can distinguish small intestinal distention from large intestinal distention with gas. Contrast radiography has been used in foals to demonstrate abnormalities of gastrointestinal transit time and gastrointestinal obstruction (see Chapters 32 and 33).

Laparoscopy

Although diagnostic laparoscopy has a sensitivity of 82% and a specificity of 66% for horses with acute abdominal pain, localized lesions or lesions inaccessible to the selected portals cannot be detected, and ileal lesions, such as ileocecal intussusception and ileal hypertrophy, can be missed.
Duodenal lesions can be seen in the standing horse. Care must be taken when inserting the trocar assembly into the abdomen in a horse with colic to avoid damage to distended viscera (for details on this technique, see Chapters 14 and 33).

**SURGICAL DISEASES OF THE SMALL INTESTINE**

In nine reports from referral institutions, 25% to 64% of all colic cases involved small intestinal diseases (Table 35-1), with a median of 34%. The ileum was involved in 41% to 46% of all small intestinal obstructions. The majority of small intestinal colics (58% to 85%) are caused by strangulating lesions, and the remainder by nonstrangulating obstruction (simple and functional obstructions). Rankings of disease prevalence must consider that the prevalence of different lesions can vary considerably between clinics (see Table 35-1).

### Nonstrangulating Obstruction

#### Ileal Impaction

Impaction of the ileum is usually a primary condition in an apparently normal ileum, but it can occur secondary to other ileal diseases. The impaction forms a doughy-to-solid, tubular mass up to 90 cm long that extends proximally from the ileocecal junction. The disease has a regional distribution in the United States, with most cases diagnosed in the Southeast, where the high prevalence may be related to feeding coastal Bermuda grass hay. Ileal impaction also occurs in parts of the United States and in Europe where coastal Bermuda grass hay is not fed. The disease appears to be more common in the United States from June through November, especially in the fall, although a seasonal effect was not found in one study. In that study, the risk for impaction was not reduced by combining coastal Bermuda hay with other hay, it appeared to be increased by recent introduction or feeding poor-quality hay, and it appeared to be lowered by feeding a pelleted-concentrate feed in addition to hay. The disease has been reported in a wide age range, including newborns and older foals. In a large series of cases, mares and Arabian Horses were significantly overrepresented.

In the United Kingdom, where coastal Bermuda grass hay is not fed, ileal impaction was strongly associated with both coprologic and serologic evidence of tapeworm infection in horses. This was supported by a study of 78 horses in North Carolina, which showed that feeding coastal Bermuda hay and failure to administer pyrantel pamoate (effective against tapeworms) placed horses at risk for ileal impaction. Mucosal ulceration and submucosal edema caused by tapeworms at the ileocecal valve is proportional to the number of parasites present and could predispose to obstruction at that site. Orbital mites are the intermediate hosts for *Anoplocephala perfoliata* and their preference for humid regions (southeast) could also contribute to the geographic predisposition to ileal impaction in the United States.

Early pain from ileal impaction is attributed to spasmodic contraction of the bowel around the impaction, but pain becomes more severe and constant as small intestinal dis-

Diseases recorded for all ages combined, but prevalence among foal diseases is also given, where available. Not all diseases were listed in all reports.

*This is an unusually high prevalence for this lesion among all small intestinal lesions, but it was the most common small intestinal lesion in this study.
tention progresses. Small intestinal distention is generally a consistent rectal examination finding, and the impacted ileum is more easily palpated early in the disease course before small intestinal distention becomes severe. Gastric reflux can be obtained in most horses but not all, depending on the duration of obstruction. Distinction between ileal impactions, strangulating obstructions, and proximal enteritis cases can be difficult (see preceding).

Medical treatment is a viable alternative if surgery is excluded by a lack of finances and can be successful early in the disease, when the impaction can be felt per rectum. Medical treatment consists of a balanced electrolyte solution administered intravenously at 5 L every 2 hours and flunixin meglumine at a rate of 0.5 mg/kg three or four times daily. Mineral oil should be administered when gastric reflux has ceased. If surgery is required, the impaction is broken down by manual massage, aided by mixing it with fluid from the proximal bowel or from saline infusion. Although dioctyl sodium sulfosuccinate has been included in the infusion, this is a very irritating drug to mucosal surfaces. Excessive manipulation can cause serosal damage and adhesions, enterotomty is contraindicated in all except rare instances, and jejunocecostomy is not recommended in the absence of a predisposing lesion or severe changes in the muscle wall.

If treated early, the prognosis is favorable, although ileus, gastric rupture, laminitis, mucosal necrosis, and perforation of the ileum are complications when the diagnosis is delayed. Re-impactions are rare. Because tapeworms may play a role in this disease, anthelmintics are recommended, such as pyrantel pamoate at 6.6 mg/kg to 13.2 mg/kg and dewormer combinations approved by the U.S. Food and Drug Administration, with praziquantel as the active ingredient against tapeworms.

Muscular Hypertrophy of the Ileum

Muscular hypertrophy of the ileum can cause ileal impaction, but it is more likely to cause recurrent colic. Unlike the muscular hypertrophy that develops proximal to a chronic obstruction, ileal hypertrophy causes marked luminal constriction (Fig. 35-4). The condition is considered idiopathic. Chronic mucosal inflammation can cause smooth muscle hypertrophy in rats, but mucosal inflammation may or may not be evident in ileal hypertrophy in horses. Ileal hypertrophy and rupture were documented in a pony distal to an ileocecostomy that had been performed 3 years previously to bypass a short, reducible ileocecal intussusception. At the time of the original surgery, that segment of ileum had been judged to be normal. The affected segment is usually 1 m long, and both the circular and longitudinal layers are increased in thickness and diverticula are common (see Fig. 35-4). Full-thickness rupture can occur. The terminal segment of ileum and the ileocecal junction are spared in some cases. The distal jejunum can undergo compensatory hypertrophy in longstanding cases but with an increase in lumen diameter.

The disease has been reported in horses over a wide age range, including foals, but it is most common in mature horses. There does not appear to be a breed predilection.

Figure 35-4 A, ileal muscular hypertrophy treated 1 year previously by side-to-side incomplete bypass. Note the prominent diverticula and tubular appearance of the ileum. Death was from a nonrelated cause. B, The horse seen in A, with jejunum and ileum opened to demonstrate the thick wall of the ileum and the narrow lumen compared with normal bowel, as well as the diverticula.
Most horses are presented with a history of recurrent, low-grade colic of variable duration, up to 2.4 years in one case.120 Partial anorexia and weight loss are common. The involved segment was palpated per rectum in 20% of horses in one study.120 Clinical findings and history are similar to those of horses with chronic ileocecal intussusception, but most cases have been described in older horses (more than 5 years).103,115,117,118,120

Side-to-side ileocecostomy or jejunocecostomy with or without transection or removal of part of the ileum (incomplete bypass) is usually successful101 (see Fig. 35-4). The stoma is made proximal to the constricted segment, and if the space between the ileum and cecum is large, it is not closed.101

Ascarid Impactions

Intestinal stages of Parascaris equorum can cause small intestinal obstruction, intussusception, abscessation, and rupture in foals and weanlings (median age of 5 months, range of 4 to 24 months).122 Affected foals usually appear parasitized and unthrifty. Impaction usually (54%) follows shortly after anthelmintic treatment.122 Ascarids in feces and in gastric reflux are of no diagnostic value because of the high prevalence of this parasite in foals. Ultrasonographic examination can demonstrate ascarids in the small intestine.89 Recent evidence that Parascaris equorum can acquire resistance to ivermectin123 could mean that foals and young horses are at increased risk for this disease.

Some ascarid impactions can be resolved manually or by typhlotomy, and these cases seem to have the best prognosis, possibly because they have minimal small intestinal damage.124 Enteroectomy is required to evacuate the impaction in more severe cases (Fig. 35-5), although resection is indicated if the bowel is devitalized101,122 Not all the worms can be removed at surgery, regardless of method, and anthelmintic treatment after surgery is recommended.124 Postoperative mortality can be as high as 92%, with focal necrotizing enteritis, peritonitis, abscess formation, and adhesions accounting for most deaths.122,124 Reasons for such a poor prognosis after surgery include undetected ascarid-induced damage in the intestinal wall, release of toxins from the ascarids, release of antigenic proteins after organophosphate-induced rupture of the cuticle, preexisting debilitation, low-grade liver disease, low-grade pneumonia, and failure to remove all worms at surgery.124

Prevention of ascarid impaction requires a sound deworming program, careful environmental management, and fecal egg counts to assess anthelmintic efficacy. Foals should be wormed at 6 weeks of age, and again at 6-week intervals for 6 months.124 In heavily parasitized foals at high risk for impaction, concurrent administration of mineral oil with an anthelmintic agent is recommended. However, the choice of anthelmintic is controversial, which reflects a lack of information on the role of anthelmintics in the disease process.124 Some recommend a rapid kill or complete paralysis to prevent impaction from worms undergoing agonal contortion (piperazine, organophosphates).124 Others recommend a slower kill that would allow gradual elimination of worms in groups too small to induce impaction (fenbendazole, ivermectin, or pyrantel pamoate).124

If ivermectin resistance is a problem, fenbendazole at 10 mg/kg PO should be effective.123

Duodenitis-Proximal Jejunitis

Duodenitis-proximal jejunitis (DPJ), also called gastro-duodenitis-jejunitis, hemorrhagic fibrinonecrotic duodenitis, proximal jejunitis, proximal enteritis, and anterior enteritis, involves inflammation of the proximal part of the small intestine, fluid accumulation in the stomach and small intestine, and endotoxemia. The cause is unknown. Severity of clinical signs varies over a wide range, and age, breed, and sex predispositions have not been established. Although usually diagnosed in horses over 1½ years of age,71 it does occur in nursing foals. The prevalence of the disease has been reported as 3% to 22% of all small intestinal colics, which is less common in some clinics than volvulus, strangulation in the epiploic foramen, and ileal impaction, and more common than strangulation by lipoma.96-99 Prevalence in California is lower than in other parts of the United States and Europe, and the disease appears to be more severe in the southeastern United States84 than in the Northeast.71

The clinical hallmark of the disease is nasogastric reflux of a large volume of fluid (usually greater than 48 L in the first 24 hours) in a horse that demonstrates signs of mild to severe pain initially and then depression.125 Most horses with DPJ have tachycardia, prerenal azotemia, dehydration, hypotension, and electrolyte abnormalities. In contrast to horses with strangulating lesions, horses with DPJ can have a fever, leukocytosis, and a greater volume of gastric reflux.73,84
After gastric decompression, a horse with DPJ usually demonstrates relief from pain and becomes quiet, and its heart rate decreases, whereas a horse with mechanical obstruction improves little if at all. On rectal examination, the degree of small intestinal distention with DPJ is subjectively less than with ileal impaction. Peritoneal fluid from horses with DPJ is rarely serosanguineous, and nucleated cell count and total protein concentration increase to a lesser extent than with a strangulating obstruction.

The most important goals in treatment of horses with DPJ are frequent gastric decompression, correction of disturbances in water and electrolyte homeostasis, and restoration of normal intestinal function. Horses must be kept off food and water until it is concluded that the condition has resolved, and attention should be paid to calcium and potassium, both of which can become depleted in horses with intestinal injury and decreased food intake. Rate of fluid administration and the types given should be largely determined by clinical and laboratory evidence of hydration status and electrolyte balance.

Flunixin meglumine can attenuate the hemodynamic responses to lipopolysaccharide (endotoxin) and reduce lipopolysaccharide-induced increases in plasma concentrations of thromboxane and prostaglandins. Nonsteroidal anti-inflammatory drugs also could block the effects of lipopolysaccharide on intestinal motility that could exacerbate or sustain ileus in horses with DPJ. Antilipopolysaccharide antibodies in plasma products, such as J5 Escherichia coli or Re Salmonella mutants could be used; however, there is some controversy regarding efficacy. The amphipathic cyclic polypeptide antimicrobial drug polymyxin B can avidly bind with the lipid A and thereby remove lipopolysaccharide from the circulation, although nephrotoxic side effects in dehydrated horses are valid concerns with use of this drug. Pentoxifylline, a methylxanthine derivative, can reduce lipopolysaccharide-induced production of cytokines and thromboxane in horses. Antibiotic use in DPJ is controversial, but horses in one study received metronidazole (2 g IV, then 1 g IV twice a day) and procaine penicillin (4.5 g IM twice a day), based on a high rate of positive cultures of gastrointestinal contents for Clostridium perfringens. Treatment could include prokinetic drugs to improve gastric emptying and small intestinal motility (see paragraphs on postoperative ileus in Chapter 39). Prophylaxis against development of laminitis should be considered, including confinement in a sand stall or on deep wood shavings and application of frog support.

Surgery is performed in at least 6% of cases. At surgery, the serosal surface of affected bowel appears smooth, with bright to dark red petechial and ecchymotic hemorrhages and mild edema. Although the prognosis is considered to be reduced by surgery in some areas in the United States, in two studies survival was similar in horses that underwent surgery as in those that did not. In a recent report, 40 of 42 horses (95%) recovered rapidly and completely after surgical decompression, suggesting that a prompt recourse to surgery could be indicated for this disease. In addition to a favorable outcome, other advantages of prompt surgical treatment are avoiding delay if a physical cause of obstruction cannot be ruled out and early return of normal circulation and peristalsis to the distended intestine. However, all forms of DPJ might not respond favorably to this treatment, and the longer period of inactivity necessitated by surgery could be a disadvantage. Also, regardless of the procedure used, horses with DPJ that undergo surgery are at risk for obstructive adhesions.

Reported survival rates for DPJ range from 25% to 94%, and recurrence is rare. Anion gap, abdominal fluid total protein concentration, and volume of gastric reflux in the first 24 hours were significantly associated with death by univariate analysis. Laminitis is a life-threatening complication of DPJ and the risk is greater in horses with hemorrhagic reflux at the time of admission. The considerable cost of prolonged medical treatment can necessitate euthanasia in protracted cases.

Neoplasia
Obstruction of the gastrointestinal tract by intestinal wall tumors is rare. Lymphosarcoma, adenocarcinoma, ganglioneuroma, intestinal carcinoid, leiomyosarcoma, and leiomyoma have been reported to cause small intestinal obstruction in the horse. Horses are presented with a single bout of acute colic or with repeated bouts of mild colic and will respond well to surgical removal of the tumor, if it is discrete, focal, and accessible. Resection of an isolated lymphosarcoma lesion can be curative, but this is generally a multiorgan disease with a grave prognosis.

Gastroduodenal Obstructions
Duodenal inflammation, ulcers, stenosis, and perforation can develop in foals, particularly those treated with phenylbutazone or subjected to stress, surgery, transportation, or illness. Foals younger than 4 months are at greater risk, although duodenal obstruction has been reported in yearlings and in an adult horse. Survival rates for DPJ range from 25% to 94%, and recurrence is rare. Anion gap, abdominal fluid total protein concentration, and volume of gastric reflux in the first 24 hours were significantly associated with death by univariate analysis. Laminitis is a life-threatening complication of DPJ and the risk is greater in horses with hemorrhagic reflux at the time of admission. The considerable cost of prolonged medical treatment can necessitate euthanasia in protracted cases.
surgery to confirm successful bypass of the obstruction. Barium in dilated bile ducts after surgery is indicative of cholangitis or cholangiohepatitis.\textsuperscript{144}

**Intestinal Inflammation and Fibrosis**

A number of diseases characterized by inflammation or fibrosis in the small intestinal wall have been identified as causes of colic in horses. Intestinal fibrosis has been reported as a cause of weight loss and colic in horses in a small geographic distribution in Colorado,\textsuperscript{145} but the disease appears to be more widespread and the signs more variable than originally reported.\textsuperscript{146} Equine proliferative enteropathy from *Lawsonia intracellularis* infection in the small intestine causes weight loss, colic, hypoproteinemia, and diarrhea in weanling foals.\textsuperscript{145,146} Although erythromycin alone or with rifampin is an effective treatment,\textsuperscript{145} resection or bypass of the affected segment may be required.\textsuperscript{146}

Eosinophilic gastroenteritis is a well-known but poorly understood cause of colic, diarrhea, and weight loss in horses.\textsuperscript{85} In one series of cases, weight loss was not a feature, but affected horses had colic from jejunal obstruction with a red intramural mass or circumferential plaque of fibroplasia and infiltration on the antimesenteric surface.\textsuperscript{85} The seasonal distribution of the cases corresponded to the grazing period, suggesting a dietary association.\textsuperscript{85} Treatment by complete or wedge resection was successful because of the focal nature of the lesions.\textsuperscript{85}

A similar but distinct cause of acute or chronic colic is characterized by small, focal to multifocal, well-demarcated areas of intestinal thickening and fibrosis that form constrictive mural bands in the jejunum and other parts of the intestinal tract.\textsuperscript{171} These are free of mucosal ulceration and granulomatous response, but they have histologic evidence of lymphocytic, plasmacytic, and eosinophilic infiltration of all layers, and most lesions are associated with the vasculature.\textsuperscript{147} Treatment with surgical resection or medical treatment with corticosteroids can be effective.\textsuperscript{147}

Pythiosis caused by *Pythium insidiosum* is a granulomatous disease, typically of skin and subcutis, that is most commonly diagnosed in the Gulf Coast states but also in the Midwest.\textsuperscript{148} Jejunal obstruction caused by *P. insidiosum* granuloma can cause weight loss and signs of mild, intermittent abdominal pain.\textsuperscript{148} Reported cases have been amenable to resection,\textsuperscript{148,149} which can be successful.\textsuperscript{149}

**Miscellaneous Simple Obstructions**

Duodenal obstruction in horses can cause severe pain, gastric reflux is voluminous, and some horses have spontaneous gastric reflux through the nostrils.\textsuperscript{70,150} Impactions of the duodenum and jejunum are rare, and causes include impacted feed material,\textsuperscript{70,153} compressed cracked corn,\textsuperscript{153} trichophytocecal,\textsuperscript{154} compacted wood fragments,\textsuperscript{155} persimmon fruit,\textsuperscript{156,157} molasses-based stable treats,\textsuperscript{158} baling twine,\textsuperscript{158} and a cholelith.\textsuperscript{159} The stomach, duodenum, and jejunum can become impacted intermittently, and weight loss can develop in horses that consume ripe persimmon fruits during fall and winter in the South.\textsuperscript{156,157} The ripe persimmons at that time are palatable to animals,\textsuperscript{157} and water-soluble tannins in the fruit form a solid phytobezoar when exposed to gastric acid.\textsuperscript{158} Diagnosis can be confirmed by identifying persimmon seeds in the gastric impaction on gastroscopy.\textsuperscript{156}

Small intestinal perforation by wire,\textsuperscript{160,161} a porcupine quill,\textsuperscript{162} ulcers,\textsuperscript{163} and unidentified causes may lead to diffuse or localized perforation, localized intestinal necrosis, and even occlusion of mesenteric vessels.\textsuperscript{160} Localized lesions can be resected.\textsuperscript{160,162} A recent report describes jejunal perforation in three young horses that were presented with fever, acute colic, depression, and hypovolemic shock.\textsuperscript{83} No cause could be identified for the discrete perforations, 1.5 cm or smaller, in an otherwise healthy segment of jejunum.\textsuperscript{53}

Congenital segmental aplasia of jejunal lymphatics may cause chyloperitoneum and colic in foals within 12 to 36 hours after birth.\textsuperscript{163,164} Resection of the thickened intestine can produce a satisfactory outcome,\textsuperscript{163} but mild cases can respond to conservative treatment. Ruptured lymphatics and chyloperitoneum can also develop secondary to tearing of postsurgical mesenteric adhesions and other intestinal lesions.\textsuperscript{166} An ileal diverticulum that is not a remnant of the omphalomesenteric structures (see later), other rare forms of intestinal malformation,\textsuperscript{168} and congenital jejunal duplications have been described as causes of recurrent small intestinal obstruction in horses.\textsuperscript{169} Extraluminal causes of simple obstruction include intra-abdominal abscesses,\textsuperscript{160} intramural hematoma (Fig. 35-6), and adhesions.

An idiopathic disease of the duodenum reported in three horses older than 12 years is characterized by mural thickening and marked distention in approximately 30 cm of duodenum.\textsuperscript{172} The distention starts 20 cm from the pylorus and ends in a contracted segment with aganglionosis, immediately proximal to the caudal duodenal flexure.\textsuperscript{171}

**Strangulating Obstruction**

**Volvulus**

Volvulus is defined as a rotation of more than 180 degrees in a segment of jejunum, or in jejunum and ileum, about the mesentery. Most are 360-degree rotations\textsuperscript{72} and involve long segments of intestine (Fig. 35-7). Volvulus may develop as a primary displacement or as secondary to preexisting...
lesions, such as an acquired inguinal hernia,\textsuperscript{79,172,173} a mesodiverticular band,\textsuperscript{174} a Meckel diverticulum,\textsuperscript{175} strangulation in mesenteric rents,\textsuperscript{174} distention from any cause, and fixation by vitelloumbilical bands\textsuperscript{176} and adhesions.\textsuperscript{177}

Primary volvulus can affect a horse of any age, but it is the most common indication for intestinal surgery in foals,\textsuperscript{102} especially those between 2 and 4 months of age (see Table 35-1). In the most common form of volvulus, the mesentery twists the intestine into distinct spirals. Volvulus nodosus is a less common form of volvulus, formed by the ileum and jejunum undergoing a 360-degree torsion that forms a mesenteric pouch in which prestenotic jejunum becomes entrapped.\textsuperscript{178,179} Distention of the entrapped bowel draws the ileum into the mesenteric pouch to form a tight loop that knots the entrapment.\textsuperscript{179} Volvulus nodosus is seen typically in foals 2 to 7 months of age,\textsuperscript{179} and it can account for 27% of small intestinal lesions that require surgery in foals.\textsuperscript{93}

Clinical signs are typical of acute small intestinal strangulating obstruction, and stacks of tightly distended small intestine can be palpated per rectum. In foals, severe pain seems to alternate with periods of depression, and the abdomen becomes markedly distended. Treatment involves correction of the volvulus, followed by resection and anastomosis (see later). Correction can be difficult in foals and adults with volvulus nodosus,\textsuperscript{178} but it can be accomplished by massaging the contents of the entrapped loop into the proximal segment, thereby allowing the bowel to be pulled through the ring formed by the ileum.\textsuperscript{179} If the bowel involved in a volvulus nodosus is necrotic, time can be saved by resecting the entire lesion without reduction, followed by a jejunocecostomy.\textsuperscript{179}

**Entrapment in the Epiploic Foramen**

The epiploic foramen, or foramen of Winslow, is the 4-cm-wide entry into the vestibule of the omental bursa from the peritoneal cavity. Its dorsal and craniodorsal boundary is the visceral surface of the base of the caudate process of the liver\textsuperscript{180} (Fig. 35-8). The portal vein contributes to the cranioventral border, and the gastropancreatic fold becomes evident as a band where it forms the ventral border of the foramen.\textsuperscript{180} From 8 cm to 18 m of intestine can become incarcerated in this space.\textsuperscript{73,78,181,182} Variations include simultaneous strangulation of two loops of small intestine, strangulation of the cecum by the involved small intestine,\textsuperscript{73} simultaneous incarceration of the cecum and jejunum, incarceration of a Meckel’s diverticulum (Littre’s hernia),\textsuperscript{74} a parietal (or Richter’s) hernia of the ileum,\textsuperscript{183} a parietal hernia of the duodenum,\textsuperscript{184} and impaction in the incarcerated segment.\textsuperscript{185} Entrapment in the epiploic foramen (EFE) can occur from right to left\textsuperscript{181}; however, one study reported left-to-right entrapment (Fig. 35-9) in all of 53 horses,\textsuperscript{73} another reported it in 138 of 143 horses,\textsuperscript{74} and another in 97% of horses.\textsuperscript{186} The ileum was involved in 66% to 72% of cases, either alone (12% to 25%) or in combination with the jejunum (41% to 60%), and involvement of the jejunum alone occurred in 28% to 34% of cases.\textsuperscript{73,74,92,186} The longer the duration of colic, the more likely that ileum will become involved in the strangulation.\textsuperscript{74}
The apparent predisposition to EFE in older horses and the predisposing enlargement of the epiploic foramen with age were not confirmed in recent studies. Horses of all ages can be affected, including foals, and horses 11 months to 3 years. In some of the larger studies, 47% to 71.3% of horses were under 11 years old, and no horse over 20 years was reported with this disease. Some studies found Thoroughbreds and Thoroughbred crosses to be at a higher risk, and males constituted 68.5% and 76% of cases in two studies. In one study from the United Kingdom, 74% of the cases were seen between November and March, mainly in January, suggesting that stabling played a role in cause of this disease. According to data from one U.S. and one U.K. university hospital, up to 68% of horses with EFE were cribbers before surgery, compared with 6% to 10.4% in the control groups, significant evidence that cribbing is associated with this disease.

Clinical findings can be confusing. In one study, 38% of horses with herniation of small intestine through the epiploic foramen did not show signs of abdominal pain at the referral hospital, and in 52% of these horses no gastric reflux was obtained. The signs of abdominal pain were sufficiently mild in one case to cause delay of referral for 2½ days. Changes in the peritoneal fluid do not always represent the extent of intestinal damage. Traction on the ventral band of the cecum is reported to induce a painful reaction in horses with the ileum incarcerated in the epiploic foramen; however, this test was not reliable in one report. With transabdominal ultrasonography, distended or edematous small intestine is found more often in the ventral right paralumbar fossa, followed by the caudal ventral abdomen and the middle right paralumbar fossa.

At surgery in most cases, strangulation in the epiploic foramen can be corrected by careful traction combined with pushing of the strangulated bowel in the same direction. Careful milking of fluid into the empty and collapsed distal segment may be necessary to decompress the strangulated bowel. If possible, nonstrangulated bowel can be drawn into the foramen so that distention of the strangulated segment can be reduced by spreading its contents into the non-strangulated bowel. To avoid tearing the dorsal aspect of the portal vein and causing fatal hemorrhage during traction, bowel should be drawn in a horizontal direction and not upward to the abdominal incision.

When bowel cannot be drawn back through the epiploic foramen by these methods, jejunum approximately 1 m proximal to the obstruction must be emptied through an enterotomy or by transection. The empty segment of jejunum is subsequently drawn through the foramen. After reduction, abnormal bowel is resected to include the transection or the enterotomy sites.

The short-term survival rate after completed surgery for EFE varies from 63% to 88%, and the long-term survival rate varies from 35% to 70%. Although these numbers compare favorably with other small intestinal strangulations, an earlier study reported 18% survival and a recent study reported 50% survival after completed surgery. In recent studies on long-term survival after colic surgery, EFE was the only categorical variable associated with decreased survival, and horses with this lesion were more than four times as likely to have relaparotomy than horses with other colics. Fatal hypoglycemia, a large thrombus in the portal vein, and areas of ischemic necrosis in the liver have been reported in a horse after treatment of an epiploic entrapment. Rupture of the portal vein is a complication of correction.

Pedunculated Lipoma
A pedunculated lipoma is a benign, smooth-walled fat tumor that is suspended by a thin mesenteric pedicle of variable length. It can be a solitary tumor, or several of them can be found in the same horse, with 90% found in the small intestine and 9% in the small colon. Some can develop in the omentum. Mesenteric lipomas are usually located close to the root of the mesentery and cause strangulating obstruction when the pedicle wraps around intestine and its mesentery (Fig. 35-10). A large lipoma attached close to the intestine can cause simple, recurrent obstruction, but this is uncommon. In general, the length of the stalk rather than the size of the tumor seems to influence the risk for strangulation.

Intestinal strangulation by a mesenteric lipoma is a disease of older horses, with a mean age of 14 to 19.2 years at diagnosis, and the youngest reported at 8 years. Incidence of lipomas is five times higher in horses older than 15 years compared with 10- to 15-year-old horses. Ponies, Arabians, and Quarter Horses have been reported to be at a higher risk, whereas Thoroughbreds are at a lower risk for this disease. Not all affected horses are overweight. Four studies revealed a significantly higher risk for geldings. Pedunculated lipomas should always be suspected in old horses with clinical evidence of strangulating obstruction, although clinical signs can be subtle and not always suggestive of this lesion. In one study, 6 of 17 horses did not show signs of pain at the referral institution. Consequently, this disease can be confused with duodenitis–proximal jejunitis, especially in horses with a large volume of reflux.

At surgery, the lipoma can be found wrapped in the jejunal mesentery, and the involved intestine can be difficult to exteriorize. Blind resection of the pedicle is necessary in many cases but carries the risk of creating a mesenteric rent and mesenteric bleeding. Spontaneous rupture of the lipoma pedicle and correction of the obstruction has been reported, based on surgical findings. Incidental lipomas with distinct pedicles should be removed with the ligate divide stapler (see Fig. 17-10), by ligation and transection. Small, broad-based tumors should not be removed because they are less likely to cause problems and their removal creates a mesenteric defect that should be sutured. A significant association between postoperative ileus and strangulation by lipoma has been reported, and published short-term survival rates for this strangulation range from 48% to 78.6%.

Intussusception
Jejunojejunal, jejunoileal, and ileoileal intussusceptions are reported in the horse. Suspected predisposing factors are segmental motility differences caused by enteritis, heavy ascarid burden, infection with the tapeworm Anoplocephala perfoliata, mesenteric arteritis, and abrupt dietary changes. A transverse enterotomy, functional side-to-side anastomosis, and pedunculated mucosal mass, such as a papilloma, leiomyoma, cryptococcal granuloma, granuloma of unknown cause, and carcinoma, can form the leading edge of a jejunojejunal intussusception in horses.

Ileocecal intussusception is the most common type and constituted 74% of all small intestinal intussusceptions in one report, with 27% of these causing chronic, intermittent colic. Chronic ileocecal intussusceptions represented approximately 1% of all surgical colic in one study. Horses with a chronic intussusception usually have a short intussusceptum that is not strangulated but causes an incomplete obstruction. Ileoileal intussusceptions usually form a short, doughnut-like lesion, and most cause chronic recurrent colic. Jejunojejunal intussusceptions (Fig. 35-11) usually involve long segments of bowel and cause complete obstruction, although short intussusceptions can cause recurrent colic.

With chronic intussusceptions, the repeated bouts of obstruction cause compensatory changes in almost half the jejunum proximal to the lesion (Fig. 35-12), including marked jejunal dilatation, even when empty; thickening of the muscular coat; and areas of ecchymosis along the...
antimesenteric surface. These changes do not appear to contribute to the obstruction.

Females accounted for six of seven (86%) intussusceptions in one study, and this was significantly different from the sex distribution in the hospital population. The female predisposition was less pronounced in five larger studies, ranging from 45% to 68%. One study reported an apparently higher risk for Thoroughbred horses, and another reported a higher risk for ponies.

Although regarded mainly as a disease of foals, intussusceptions have been reported over a wide age range up to 24 years, with few reported in young foals. Intussusceptions were the most common cause of surgical colic in horses 3 to 12 months of age in one study, particularly ileocecal intussusceptions. In younger foals, intussusceptions were less common and only jejunojejunal intussusceptions were recorded. Ileocecal and ileoileal intussusceptions, both of which are more likely to cause recurrent mild to moderate colic, are more common in horses 3 years of age and younger.

Intussusceptions of long segments cause signs of severe small intestinal obstruction. Short intussusceptions cause colic that is mild, intermittent, and usually postprandial, and they also cause reduced appetite and feces, elevated temperature, weight loss, and failure to thrive compared with herdmates. An ileal intussusception should be strongly suspected in a horse between weaning and 3 years of age that is unthrifty and has a history of recurrent mild colic.

Rectal examination may reveal distended loops of small intestine, and the intussusception can be palpated as a firm, painful, tubular structure in some cases. Ileocelecal intussusceptions were palpated in the right dorsal quadrant of the abdomen in 31% of horses in one report and in 50% in another. During an episode of pain in a horse with a chronic intussusception, the hypertrophied small intestine proximal to the obstruction (see Fig. 35-12) can be palpated per rectum as large-diameter, moderately distended loops with thick walls. In young horses and foals too small for rectal palpation, a cross-sectional view of a jejunojejunal or ileocecal intussusception can be seen on ultrasonography as concentric rings with a bull’s-eye appearance.

White blood cells and protein concentration may be increased in the peritoneal fluid of horses with acute ileocecal intussusceptions and jejunojejunal intussusceptions. Peritoneal fluid protein concentration alone can increase in chronic ileocecal intussusceptions. In one study, 8 of 16 horses with acute ileocecal intussusceptions had serosanguineous fluid.

SURGERY: ILEOCECAL, AND ILEOILEAL INTUSSUSCEPTIONS

In chronic intussusceptions of ileum, short segments (approximately 10 cm) are involved. Reduction is difficult, even in the absence of adhesions, because of chronic folding of the intestinal wall. Reduction was impossible in 11 of 16 ileoileal intussusceptions and in 6 of 7 chronic and 10 of 19 acute ileocecal intussusceptions. Ileocecal and ileoileal intussusceptions have been treated successfully by reduction only or by reduction and myotomy. Incomplete bypass by ileocecostomy is recommended if there are concerns about permanent ileal changes and the risk of recurrence, and a hand-sewn technique is recommended over stapling instruments because the ileal wall is so thick. There is no need to resect the involved ileum in chronic cases or the hypertrophied jejunum.

Ileocecostomy for chronic ileocecal intussusception has excellent short-term results, but apparently rare long-term complications include stomal impaction, ileal hypertrophy, and rupture distal to the stoma. Also, the size of the stoma can become smaller over time, which could predispose to these complications.

In acute cases, the intussuscepted ileum and jejunum can be too edematous and hemorrhagic to allow reduction. Bypass by a jejunocecostomy without reduction can cause postoperative hemorrhage. Removal of the intussusceptum
through a typhlotomy can cause severe contamination, although suturing an impermeable plastic drape around the typhlotomy can contain leakage. In a technique devised to facilitate this surgery, the jejunum proximal to the intussusception is transected with the GIA or the ILA stapler as close to the ileocecal junction as possible. A 10-cm incision is made in the cecum to allow the intussusception to be exteriorized, and another incision is made through the outer wall of the intussusceptum to expose the inner loop (Fig. 35-13). This inner loop then is pulled through the incision in the outer layer until the closed transected end is distal to the selected site for transection. If too much bowel is drawn through this incision, or if the jejunal transection was made far from the ileocecal junction, mesenteric vessels will tear and cause fatal hemorrhage. Much of the necrotic bowel is removed by incision along the edge of a TA-90 stapler applied across the inverted ileum within the cecum (see Fig. 35-13).

SURGERY: JEJUNOJEJUNAL INTUSSUSCEPTION
A jejunojejunal intussusception forms a corkscrew configuration because of tension on the mesentery of the intussusceptum, and short to long segments can be involved. Reduction is accomplished by slow traction on the intussusceptum and gentle massage of the distal end of the intussuscipiens. If it is nonreducible, the entire intussusception can be removed by resection only, although this can make ligation of mesenteric vessels difficult.

Prognosis is favorable for all intussusceptions, but the bowel wall and intussuscepted mesenteric vessels can be torn during reduction. Some horses can have a protracted recovery after surgery for a chronic ileocecal intussusception, with slow weight gain and mild episodes of colic. Because A. perfoliata may be involved in the pathogenesis of ileocecal intussusceptions in horses, the treatment of affected horses and pasturemates with pyrantel pamoate and praziquantel is recommended.

Mesenteric Rents
Mesenteric rents can be congenital in origin, secondary to mesodiverticular bands (Fig. 35-14), or may develop as primary lesions of unknown cause. Trauma or mesenteric stretching by another lesion may play a role, and some can develop years after a small intestinal surgery at a site remote to the anastomosis. Horses of a wide age range appear to be prone, although females are more likely to be affected, especially in the postpartum period when the tear is possibly induced by vigorous movements of the foal, as has been implicated in tears of the small colon mesentery. Such tears in postparturient mares can cause segmental ischemic necrosis of the related segment of jejunum or predispose to later strangulation of a more distant portion of small intestine. The jejunal mesentery is involved in most cases, although tears in the ileal and duodenal mesentery have been reported, as well as tears in multiple sites.

Prognosis for surgical treatment appears to be worse than after other strangulating lesions of the small intestine. Possible reasons for this are inability to reduce the hernia, the long segments of bowel involved, hemorrhage from the affected mesentery, and failure to close all of the mesenteric defect. Closure of the entire defect can be difficult or impossible through a ventral midline approach. Elective laparoscopic closure of the full defect can be accomplished as a standing procedure shortly after the ventral midline celiotomy is performed to treat the original strangulation. Both sides of the abdomen may need to be examined to locate the tear.

Inguinal Hernia
An indirect inguinal hernia is the most common form in horses, and it involves small intestine passing through the vaginal ring into the vaginal tunic (see also Chapter 36). In the less common direct inguinal hernia, jejunum and occasionally the testicle escape through a rent in the peritoneum and transverse fascia, adjacent to the vaginal ring, to lie in the subcutaneous space of the scrotum and prepuce.
Direct inguinal hernias are more common in foals than in adults, but they can involve greater lengths of intestine in adults than are recorded with indirect hernias. Indirect inguinal hernias in adult horses involve short segments of small intestine (median of 15 cm) and are usually acquired and nonreducible, whereas congenital inguinal or scrotal hernias in foals involve long segments and are reducible. In acquired hernias in adults, the loop of intestine rarely advances to the level of the testicle before it becomes strangulated, whereas a variable length of intestine (approximately 1 m) can reach the fundus of the vaginal tunic in foals and remain viable (Fig. 35-16). This difference can be attributed to the shorter, wider, and more direct configuration of the foal’s inguinal canal. Contrary to popular misconception, the size of the external inguinal ring is irrelevant to development of an inguinal hernia, because it is the last structure for the bowel to traverse and is always sufficiently large for intestine to negotiate easily. The vaginal ring is the first structure to be negotiated by herniated intestine, but the intestine is actually strangulated in an adult horse by a ring 2 to 3 cm further distally, formed by merging of the internal spermatic fascia into loose connective tissue in the neck of the vaginal process.

Ileum, alone or with jejunum, was involved in 49% to 53% of adult inguinal hernias in three reports, but jejunum was involved in eight of eight horses in another. Ileal involvement may be more likely with increased duration of strangulation.

Many breeds can be affected, but a higher prevalence of inguinal/scrotal hernia has been reported in Standardbreds, Tennessee Walking Horses, and American Saddlebreds. Standardbreds also appear to be at a higher risk for intestinal eventration after an open castration. In acquired inguinal hernias, almost all age groups over 1 year are at risk. Predisposing factors are not always evident but include a history of recent strenuous exercise, recent breeding, and trauma. Direct and indirect inguinal hernias are rare in geldings.

Congenital scrotal hernias are noted shortly after birth, are easily reduced when the foals are rolled onto their backs, and usually resolve spontaneously within 3 to 6 months. Intestinal strangulation is rare. Although the problem is usually unilateral, bilateral cases can occur. Direct or ruptured inguinal hernias in foals are evident within 4 to 48 hours after birth and cause intermittent colic, depression, severe scrotal and preputial swelling (see Fig. 35-15), and edema, with skin excoriation and splitting caused by abrasion against the inside of the thigh. These hernias are not reducible and are treated as surgical emergencies, although strangulation is rare.

Acquired inguinal hernias in adult horses cause signs of mild to severe colic. As it becomes strangulated, the intestine compresses the testicular vessels and causes the testicle to become swollen, firm, and cold. Although the strangulated intestine may not be evident on external examination, rectal examination reveals small intestine entering the vaginal ring and distention of the small intestine. Bilateral cases are very rare. Ultrasonography can facilitate early diagnosis and is especially useful if rectal palpation is not possible.

**Surgery: Congenital Hernias**

Surgical correction is indicated if the hernia does not resolve spontaneously. The owner is concerned because of an apparent increase in size of the hernia, or the vaginal tunic ruptures. Surgical correction can be accomplished in foals through an inguinal approach with exposure of the tunic and its contents (see Fig. 35-16), removal of the cremaster muscle, twisting of the testicle and tunic to force the bowel into the abdomen, and then closed castration combined with a transfixation ligature of 0 polydioxanone through the tunic (see Chapter 38). Closure of the external inguinal ring is suggested but not essential and may not prevent...
re herniation.\textsuperscript{227,229} Alternative methods are laparoscopic repair with\textsuperscript{239} or without castration,\textsuperscript{240} an inguinal approach without castration,\textsuperscript{241} or a midline celiotomy with closure of the vaginal ring. The testicle can atrophy after the latter two methods.

For repair of a direct or ruptured inguinal hernia in foals, the torn edges of the common vaginal tunic are identified and drawn upward to create a funnel through which the bowel is returned to the abdomen. The bowel can be directed into the abdomen by careful digital manipulation or by grasping the bowel in unclosed sponge forces. The torn tunic should be repaired as much as possible to the level of the vaginal ring. Usually, the intestine is viable and does not require resection, although delayed necrosis has been reported.\textsuperscript{227} Castration facilitates the repair and closure of the vaginal tunic.

**SURGERY: ACQUIRED HERNIAS**

In the early stages, a direct hernia in an adult may correct spontaneously after the anesthetized horse is placed in dorsal recumbency\textsuperscript{226} or can be corrected by applying gentle traction to the bowel per rectum,\textsuperscript{234} with or without external massage of the scrotum.\textsuperscript{242} External massage alone may also be effective and can be guided by laparoscopy,\textsuperscript{232} which also allows assessment of intestinal viability. In such cases, laparoscopic inguinal herniorrhaphy may be performed 1 week later to prevent recurrence, using either a mesh onlay graft\textsuperscript{242} or a cylindrical mesh plug.\textsuperscript{243} Spontaneous reduction or reduction by traction does not rule out the possibility of complications from progressive intestinal necrosis.\textsuperscript{229}

A nonreducible inguinal hernia is corrected through an inguinal incision directly over the external inguinal ring and along the spermatic cord. The abdomen should be prepared for a ventral midline celiotomy, if needed, to allow intrabdominal traction on the bowel, to assess viability of the released bowel, to decompress or examine proximal bowel, or for a jejunoccecal anastomosis. The tunic is dissected from the surrounding tissues, with care taken to not damage the pudendal vein and branches. A cranial incision is made in the vaginal tunic, which needs to be extended far enough distally to cut the constricting ring formed by the internal spermatic fascia and release the strangulated intestine.\textsuperscript{232}

The tunic edges should be grasped with hemostats to maintain access for closure. Medial and cranial retraction on the edge of the internal abdominal oblique muscle with a Deaver retractor will improve exposure to the tunic edges, and a finger is used to direct bowel away from the suture line.

Because short segments (less than 25 cm) of intestine are usually involved,\textsuperscript{225,228} resection is rarely needed if appearance of the bowel improves markedly after the strangulation has been released. A unilateral castration is recommended to allow more complete closure of the vaginal tunic and abolish the risk of recurrence.\textsuperscript{234} In addition, the involved testicle can become cystic or nonfunctional in time, and postoperative swelling could induce degeneration of the other testicle. Techniques to correct the hernia and prevent recurrence have been described.\textsuperscript{240,244}

If the vaginal ring can be closed, closure of the external inguinal ring is not essential and does not ensure against evisceration.\textsuperscript{229} However, if the vaginal ring closure is not secure, closure of the external inguinal ring is recommended. Closure of the thick subcutaneous fascia and skin incision is accomplished in two layers. After surgery, the scrotum on the castrated side usually lies against the prepuce, and swelling is minimal. Any method of correction that does not involve exploration of the abdomen would fail to detect a concurrent small intestinal volvulus, a rare complication of inguinal hernia that could cause postoperative colic.\textsuperscript{179,171,173}

A survival rate of up to 76% has been reported for acquired inguinal hernia.\textsuperscript{229,232,234} Adhesions at the vaginal ring are rare causes of later strangulation.\textsuperscript{233}

**Incarceration through the Gastroplenic Ligament**

The gastroplenic ligament is a broad but thin attachment between the left part of the greater curvature of the stomach and the hilus of the spleen.\textsuperscript{1} Small intestine can pass from caudal to cranial through acute tears in this ligament so that the strangulated loop is lateral to the stomach and cranial-lateral to the spleen\textsuperscript{245} (Fig. 35-17). At surgery, the strangulation is easily corrected by traction, and enlarging the rent does not cause problems or predispose to recurrence. If the most ventral edge of the defect in the ligament is accessible, it can be transected between two ligatures to disrupt continuity of the ring.\textsuperscript{246}

**Vitelline Anomalies**

A mesodiverticular band develops from a vitelline artery and associated mesentery that fail to atrophy during early embryonic development.\textsuperscript{174} The band is usually found in the distal jejunum, approximately 1.5 m from the ileocecal junction. It extends from one side of the mesentery, usually the left, to the antimesenteric surface of the small intestine to form a triangular space (see Fig. 35-14). Intestine may

![Figure 35-17. The jejunum is strangulated in a rent in the gastroplenic ligament and lying in the left cranial part of the abdomen. S, spleen.](Image)
become strangulated in a mesenteric rent that forms in that space (Fig. 35-18), and secondary volvulus of the small intestine follows. A mesodiverticular band alone can also cause a volvulus because the band shortens the mesentery at the point of attachment. Although a mesodiverticular band represents a congenital anomaly, it can cause obstruction in mature horses and may be an incidental finding at necropsy.

Meckel’s diverticulum is a remnant of the omphalomesenteric (vitelline) duct that provides a communication between the yolk sac and early embryonic gut. It forms a conical blind extension from the antimesenteric surface of the distal jejunum or ileum, 40 to 120 cm from the ileocecal junction (Fig. 35-19). It can be up to 35 cm long, but it is usually 10 to 15 cm long and 5 to 10 cm in diameter. Occasionally, a fibrous band persists from the apex of Meckel’s diverticulum to the umbilicus—the vitelloumbilical band—and creates an axis for volvulus of the jejunum and ileum.

In one review of 15,000 necropsies, Meckel’s diverticulum was responsible for the death of all five horses (0.03%) in which it was found. Meckel’s diverticulum can become impacted and achieve enormous proportions or become necrotic and rupture to cause fatal peritonitis. Meckel’s diverticulum can also entangle and strangulate small intestine or form an axis for volvulus nodosus. In one horse, a Meckel diverticulum was found adhered to and impacted in an umbilical hernia, thereby forming a Littre hernia. Although Meckel’s diverticulum represents a congenital anomaly, it can cause colic in horses of a wide age range.

**Strangulated Umbilical Hernia**

Strangulation of a loop of small intestine in an umbilical hernia is rare, and the involved intestine can rupture through the hernial sac and dissect subcutaneously in a caudal direction to cause an inguinal enlargement (see also Chapter 38). More commonly, only a portion of the antimesenteric wall of the ileum is incarcerated, and this is termed a parietal, or Richter’s, hernia. A parietal hernia should be suspected when an umbilical hernia becomes nonreducible, large, turgid, edematous, and painful to palpation. A parietal hernia can cause umbilical abscessation, which may lead to rupture of the hernia and formation of an enterocutaneous fistula. Ultrasonography may be used to evaluate the hernia and its contents. Colic can develop in horses with a parietal hernia, but it is not observed in all cases of an umbilical abscess or enterocutaneous fistula. Surgical correction of these umbilical lesions is successfully accomplished by making a 10- to 15-cm celiotomy cranial to the ring, and digitally guiding en bloc removal of the umbilical lesion through this incision. Resection and anastomosis of involved intestine may be required.

**Diaphragmatic Hernias**

A diaphragmatic defect can be congenital in origin or acquired, although the distinction is difficult. Small intestinal strangulation in diaphragmatic defects has been reported in foals as causes of death at 7 hours to 8 days after...
birth. A congenital diaphragmatic defect or a diaphragmatic tear inflicted by a rib fracture, usually at or close to the costochondral junction of ribs 3 to 8, are likely causes of diaphragmatic hernia in foals.* Small defects are more likely to be strangulated if the hernia is present at birth. Although several abdominal organs can enter the diaphragmatic defect, small intestine is the most commonly reported. There does not appear to be an age, breed, or sex predisposition to this disease.

Large defects are more likely to cause dyspnea from pulmonary compression by intrathoracic displacement of the colon, but they do not incarcerate bowel and cause colic. Small defects are more likely to strangulate small intestine and manifest as acute and severe colic, clinically indistinguishable from strangulation by any other cause. Abnormalities can be detected on auscultation and percussion of the thorax in some horses.

Both radiography and ultrasonography allow preoperative diagnosis. Ultrasonography may be superior to radiography in evaluating diaphragmatic hernias in horses, especially for small tears with little visceral displacement, or when pleural effusion obscures the ventral portion of the diaphragm. The diaphragm can be imaged with 5- or 7.5-MHz transducer adjacent to and parallel with the body wall ventrally, then diverging dorsally and medially to lie behind the echogenic lung. The curved shape of the diaphragm may prevent complete evaluation.

SURGERY

A diaphragmatic hernia can be missed at surgery. If strangulated bowel is found free in the abdomen, a careful search must be conducted to ensure that it did not fall out of a diaphragmatic defect when the horse was placed in dorsal recumbency.

Ideally, a respirator should be used to provide controlled positive-pressure ventilation and correct the diminished pulmonary function. An advantage of preoperative diagnosis is that the abdominal incision can be placed further cranially than the standard approach. Access to ventral defects is not difficult, but access to more dorsal defects can be improved by extending the cranial end of the incision laterally for approximately 12 to 15 cm at an angle of 60 to 90 degrees in a paracostal fashion. The table can be tilted to raise the cranial end of the horse’s abdomen so abdominal contents can fall away from the diaphragm.

A small defect may have to be enlarged with scissors or a curved feto
tome to release the bowel. Most defects can be closed with a continuous pattern using heavy absorbable or nonabsorbable material, and the suture line should be completed at full inspiration to reduce the pneumothorax present. Mesh coverage is required for defects that cannot be sutured because of their large size or because the edges are too firm to allow apposition. Successful repair of a dorsal rent that was inaccessible for suture placement was accomplished by blind fixation of a doubled polypropylene mesh (Marlex Mesh #1266, Dowd Inc, Providence, RI) with 4-mm stainless steel staples (Disposable Skin Stapler, Richard-Allen Medical, Richland, Mich). Another inaccessible defect was repaired in the standing horse by suture closure through a thoracic rib resection that was placed by guidance from thoracoscopy and manual direction through a flank incision. Indwelling chest tubes covered by a Heimlich valve (see Chapter 18) can be placed to correct pneumothorax and fluid accumulation in the chest.

Successful repairs of diaphragmatic hernias have been reported in adult horses and foals and in horses can race, participate successfully in various forms of competition, and deliver foals after repair. One horse with a small defect that was inaccessible for repair returned to a full athletic career. Unrepaired diaphragmatic defects can partly seal by adhesion of adjacent stomach and liver to the edges, although recurrence of intestinal incarceration immediately after anesthetic recovery is also likely.

Miscellaneous Strangulating/Ischemic Diseases

Small intestine can become strangulated in mesenteric ligamentous bands that cannot be exteriorized at surgery and must be cut blindly with scissors. Small intestine can also become strangulated by uterine torsion; through rents in the mesometrium; gastrohepatic ligament, small colon mesentry, lateral ligament of the urinary bladder, cecocolic fold, and mesentery of the large colon; by components of the spermatic cord, particularly the mesoductus deferens; and by omental adhesions. Evisceration through a lacerated vaginal fornix, a defect in the bladder and urethra, or a castration wound may cause small intestinal strangulating obstruction. Entrapment of small intestine within the nephrosplenic space has been reported in two horses, with the bowel passing from cranial to caudal. Both horses were presented alert and in stable condition, and the affected segments of bowel did not require resection. Mesenteric hematomas of unknown cause can cause colic and ischemic necrosis of affected intestine. Surgical access to the source of hemorrhage may be difficult. Duodenal torsion has been reported but is rare.

Adhesions after small intestinal surgery or any intraabdominal procedure can form an axis around which attached small intestine can form a volvulus, or adhesions can form fibrous bands through which small intestinal loops can become strangulated. Nonstrangulating infarction and necrotizing enterocolitis in the small intestine are rare and have a poor prognosis.

Surgical Techniques

Success of small intestinal surgery in the horse is dependent on (1) identification and correction of the primary problem, (2) intraoperative decompression of distended small intestine, (3) resection of all abnormal intestine, (4) preservation of anatomic and physiologic continuity of the intestine, (5) rapid completion of the surgery with minimal trauma, (6) early return of intestine to normal function, and (7) appropriate postoperative support, including repeat laparotomy when indicated.

If the lesion is not revealed quickly by a cursory examination of the abdomen, the cecum should be found and the ileocecal fold traced to the ileum, followed by progressive examination of the jejenum in a cranial direction until the involved segment is found. If several discontinuous loops of small intestine are exteriorized through the incision, they form tight bands of mesentery that can prevent extraction of other distended loops. Rarely, a horse may have two apparently unrelated, strangulating lesions of the small intestine.173,280 However, it is more common for a horse to have a concurrent large intestinal lesion, such as volvulus, displacement, or impaction.72,158

Viability Assessment

Viable small intestine refers to the ability of intestine to survive without developing adhesions (for additional information, see Chapter 34). The observation that increased duration of surgery and length of bowel resected can adversely affect prognosis provides impetus to improve viability assessment and thereby avoid resection whenever possible.197 Clinical criteria of viability are serosal color, improvement in color after correction of the strangulation, presence or absence of mesenteric arterial pulses, and intestinal motility, spontaneous or evoked (by snapping a finger against the intestinal wall). Clinical judgment tends to be pessimistic. Fluorescein fluorescence offers little improvement over clinical judgment but is accurate when it produces a viable fluorescent pattern.281

Intestine can be considered viable if the predominant clinical findings are hemorrhage and edema in the bowel wall, especially if the color improves within approximately 15 minutes after release of the obstruction.282 Spontaneous or evoked motility appears sluggish in viable strangulated bowel because of “splinting” of the muscle wall by edema and hemorrhage. Enterotomies are not recommended for viability assessment in the small intestine because of the risk for adhesion formation and because mucosal changes are usually sufficiently severe to cause an incorrect prediction in viable bowel. With long segments of questionable viability, the risk for adhesions must be balanced against the risks of additional anesthesia time and the occurrence of adhesions after resection and anastomosis.

Resection

After the lesion has been corrected, the bowel must be arranged in its correct orientation and then decompressed, if necessary. Decompression is accomplished through the strangulated bowel, but only after the bowel has been freed from its mesentery and mobilized from the surgical field. For this purpose, a ligature of 3-0 polydioxanone (PDS) is applied to the first mesenteric vessel in the strangulated bowel, level with the proposed line of mesenteric resection. The mesenteric vessel is then transected distal to the ligature with the ligate divide stapler (LDS) (see Fig. 17-10). The short end of the ligature is secured with a hemostat, and the long end is used to gather the trimmed edge of mesentery as each mesenteric vessel is transected with the LDS instrument (Fig. 35-20). Ideally, the line of mesenteric resection should remain at a constant distance from the bowel, because any deviation toward the mesenteric root will short-en the mesentery and kink the bowel.195 The two ends of the suture are tied to close the gathered mesentery after the bowel is decompressed, and a gap will remain to be closed between the bowel and the line of mesenteric resection (see Fig. 35-20). With this method, any bleeders can be retained in view outside the abdomen, and a large mesenteric gap is avoided that would allow rotation or entrapment of bowel.195

The nonviable intestine can now be exteriorized from the abdomen, far from the surgical field, to drain into a container, taking care not to stretch and tear remaining mesenteric attachments. As much intestine as possible proximal to the site of transection is manually stripped of its fluid and gas contents, with care taken not to tear the mesentery (Fig. 35-21). This amount of intestinal handling does not appear to predispose to adhesions, and decompression seems to minimize problems with postoperative ileus. If resection is not needed, small intestinal distention should be relieved through a typhlotomy and not a small intestinal enterotomy, because the latter may lead to adhesion formation and obstruction.

Strangulated bowel is removed along with approximately 30 to 50 cm of contiguous healthy intestine at each end. A large arcuate artery, approximately 10 cm from its origin from the major mesenteric vessel, is left to supply the anastomosed ends. Approximately 2 to 10 cm of mesentery is left beyond the last major vessels and branches to prevent inadvertent vascular occlusion or puncture during closure of the mesenteric gap. After the anastomosis is complete, the
The bowel is lavaged. The defect remaining in the mesentery is closed with 2-0 or 3-0 PDS in a simple continuous pattern, with care taken to avoid mesenteric vessels or creating an accordion effect that could kink the bowel. If the mesenteric stump is inflamed and hemorrhagic, adjacent healthy mesentery can be wrapped around it.

Hand-sewn End-to-End Jejunoejunostomy

To prevent leakage into the surgical field, a Penrose drain may be applied at least 15 cm proximal to the anastomosis site to avoid trauma to this critical area (Fig. 35-22). Penrose drains are less traumatic than Doyen clamps and facilitate manipulation and positioning of the bowel. To create a large stoma, the intestine should be transected at approximately 50 to 60 degrees from the mesenteric attachment; an S-shaped line of transection will increase the diameter further without creating sharp angulations in the incision edges. A suture is placed through the mesenteric and antimesenteric edges of both segments to draw them into alignment and to maintain them at similar diameters. With all end-to-end anastomoses, special care must be taken to appose the mesenteric border first, because rapid edema formation at this area can make it difficult to identify the seromuscular layer.

A popular method for end-to-end anastomosis of equine small intestine is a two-layer continuous pattern. This involves a simple continuous pattern of 2-0 or 3-0 absorbable suture for the submucosa/mucosa, followed by a continuous Lembert or Cushing pattern in the seromuscular layer (see Fig. 35-22). The Lembert pattern can be placed so as to produce minimal inversion. Mucosal and seromuscular rows are interrupted at the mesenteric and antimesenteric margins or at thirds of the circumference to prevent a purse-string effect. The Cushing pattern exposes less foreign material to the serosa and therefore poses less risk for adhesion formation than the Lembert pattern, but the Cushing is more likely to pursestring the bowel. The degree of inversion is greater with the Lembert pattern, so special care is needed to minimize this effect (see Fig. 35-22). Combinations of patterns that involve two layers in the seromuscular wall, such as continuous appositional, Lembert, Cushing, or Connell oversewn with Lembert or Cushing, produce excess seromuscular inversion, stomal constriction, and a

Figure 35-21. A method of stripping the distended bowel to decompress it.

Figure 35-22. A and B, The lumen of the small intestine is occluded temporarily with a Penrose drain proximal to the anastomosis site. A one-layer closure consisting of interrupted Lembert sutures is carried out. C, Close-up of an alternate (two-layer) anastomosis technique: a simple-continuous apposition of the mucosa over three times a third of the circumference, followed by a minimal inversion pattern of the seromuscular layer.
high risk for postoperative obstruction. There is ample evidence that single-layer anastomoses work well in equine small intestine (for additional details on suture patterns, see Chapter 17).285

The Gambee and other interrupted patterns are more likely to cause anastomotic adhesions in the horse than continuous patterns,283,286 although results of one study did not confirm this.284 Larger sizes of suture material, such as 0 PDS or polyglactin 910 (Vicryl),283,286 could predispose to adhesions because they place a greater volume of foreign material along the anastomosis than 3-0 PDS, which is preferred.285 An interrupted Lembert pattern is used with approximately 6- to 8-mm bites that penetrate within 1 mm from the cut edge of the seromuscular layer and are 6 to 8 mm apart (Fig. 35-23). This pattern may be less likely to induce adhesions than the Gambee method, and it is quicker.

A single-layer anastomosis with 3-0 PDS through the full thickness of the equine jejunum and wrapped with a sodium carboxymethylcellulose and hyaluronate membrane was faster than mucosal closure followed by a Cushing pattern.285 Also, the single-layer anastomosis reduced lumen diameter from normal adjacent lumen by 35.6%, compared with a 44% reduction for mucosal closure and a Cushing pattern.285 It also developed significantly fewer peri-anastomotic adhesions than a single-layer anastomosis without the membrane.285 With this single-layer pattern, care must be taken to minimize mucosal eversion, because mucosa does tend to protrude between the seromuscular edges,285 which could lead to adhesion formation.

Figure 35-23. End-to-end anastomosis with interrupted Lembert sutures before the mesentery is closed. Note the darker discoloration of the bowel to the right, which is caused by prestenotic distention.

**Stapled Jejunojejunosotomy**

The major advantages of stapling instruments are speed, reduced tissue handling, improved tissue blood flow, and minimal contamination.287 If the staple line is oversewn, the first two advantages are lost and the prevalence of adhesions becomes comparable to that with hand-sewn anastomoses in horses.287 The most important disadvantage of staples is expense. The security of the closure with staples can be enhanced by hand-sewn techniques, although results of one study did not confirm this.282 Larger sizes of suture material, such as 0 PDS or polyglactin 910 (Vicryl),283,286 could predispose to adhesions because they place a greater volume of foreign material along the anastomosis than 3-0 PDS, which is preferred.285 An interrupted Lembert pattern is used with approximately 6- to 8-mm bites that penetrate within 1 mm from the cut edge of the seromuscular layer and are 6 to 8 mm apart (Fig. 35-23). This pattern may be less likely to induce adhesions than the Gambee method, and it is quicker.

A single-layer anastomosis with 3-0 PDS through the full thickness of the equine jejunum and wrapped with a sodium carboxymethylcellulose and hyaluronate membrane was faster than mucosal closure followed by a Cushing pattern.285 Also, the single-layer anastomosis reduced lumen diameter from normal adjacent lumen by 35.6%, compared with a 44% reduction for mucosal closure and a Cushing pattern.285 It also developed significantly fewer peri-anastomotic adhesions than a single-layer anastomosis without the membrane.285 With this single-layer pattern, care must be taken to minimize mucosal eversion, because mucosa does tend to protrude between the seromuscular edges,285 which could lead to adhesion formation.

**Side-to-Side Stapled Jejunojejunosotomy**

The isoperistaltic side-to-side technique involves creating blind stumps of the proximal and distal ends of the jejunum with either a Parker-Kerr technique (see Fig. 17-6) or stapling instruments (see Figs 17-11 and 17-12). The gastrointestinal anastomosis (GIA) instrument is used to create the stoma in the overlapped segments. This places two parallel rows of staggered staples on each side of a stoma cut simultaneously by advancement of the knife blade (Fig. 35-24). If the GIA-50 is used, it is placed proximally and then distally through the same stab incisions on the antimesenteric side, effectively doubling the size of the stoma. Care must be taken to ensure that the staple lines overlap on the far side of the stab incisions or that any defect on that side is oversewn. If the Multifire GIA-80 or ILA-100 (United States Surgical Corp, Norwalk, Conn) is used, a single application is sufficient. The two mesenteric edges are sutured to the adjacent mesenteric surfaces at the points of overlap.

**Functional End-to-End Stapled Jejunojejunosotomy**

With the functional end-to-end anastomosis, the bowel ends are lined up in antiperistaltic fashion, the stoma is created with the GIA instrument along apposing surfaces, and bowel ends are closed.285 A closed, stapled, one-stage, end-to-end jejunojejunosotomy realigned itself into an end-to-end configuration as it healed and did not cause adhesions in normal horses.286 Intussusception of a functional end-to-end anastomosis has been reported in ponies at 2 and 26 days after surgery and in a horse at 8 months after surgery.287
Jejunocecal and Ileocecal Anastomoses

Jejunocecal and ileocecal anastomoses are indicated when a portion of the ileum is involved in a strangulating lesion. These techniques can constitute 36% to 68% of all small intestinal anastomoses. Proponents of the side-to-side jejunocecostomy believe that it creates a larger stoma than is possible with the end-to-side technique and that it is associated with fewer postoperative problems from stomal edema. In a study that compared the two techniques in clinical cases, 83% of horses with a side-to-side jejunocecostomy were discharged from the clinic, compared with 37% that had an end-to-side jejunocecostomy. The latter also had more repeat celiotomies, necessitated by such complications as bowel kinking at the anastomosis, adhesion formation, impaction, intussusception of the anastomosis, and volvulus or torsion. An angled line of transection of the jejunum or ileum, with or without a longitudinal incision on the antimesenteric side, allows construction of a stoma of adequate size with the end-to-side technique.

The mesentery and small intestine are prepared as for an end-to-end anastomosis except that the ileum is transected and oversewn using either stapling instruments or a Parker-Kerr technique (see Fig. 17-6). The ileal stump should be as short as possible, because an intussusception can form into the cecum over time. A long stump can progress into and obstruct the cecocolic orifice. The ileal stump remains nonfunctional and therefore can tolerate more severe ischemia than would be acceptable in bowel that is expected to regain normal activity. One method proposed to reduce problems from an ischemic stump is to suture omentum over the suture line.

For extensive ileal necrosis, the TA-90 can be used for a distal transection down to the ileocecal orifice. The 4.8-mm-length staples are recommended for this purpose. An incision is made in the mesentery dorsal to the ileal artery and in the ileocecal fold, and it is continued to the level of ileal transection to create a tract for passage of a loose ligature to that point. This ligature is tied to compress all mesenteric tissues at the level of transection, including the ileal artery and vein. The disadvantage of this and other methods of deep ileal transection is that they create a large mesenteric defect that could entrap bowel. An alternative method is to attach the ileum to a length of stomach tube that can be used to invert the necrotic stump into the cecum.

End-to-Side Anastomosis

The stoma should be created as close to the base of the cecum as possible to reduce the gravitational effects of cecal contents. The stoma is made midway between the dorsal band and the medial band, and the small intestine is aligned so that it is directed toward the base of the cecum (Fig. 35-25).

A noncrushing intestinal clamp can be used to clamp off a pouch of the cecum, or upward tension on stay sutures or on Babcock forceps can be used to maintain the cecal opening above the cecal contents. After the mesenteric and antimesenteric ends of jejunum are attached to the selected area on the cecum by simple-interrupted sutures of 3-0 PDS, a Lembert or Cushing pattern apposes the back side of the jejunum to the cecum. An incision is then made in the cecum 5 mm from the suture line that corresponds with the opening in the jejunum. The next row is a simple-continuous, full-thickness pattern, interrupted at the mesenteric and antimesenteric borders before it is continued for 360 degrees. A Cushing or a continuous Lembert pattern on the near side completes the anastomosis. The free edge of mesentery is sewn to the cecum and then to the ileocecal fold, ending at the oversewn end of the ileum.
previously gathered mesenteric stump (see Fig. 35-25). Failure to close this mesenteric defect can lead to subsequent passage of small intestine through it, followed by obstruction and even strangulation.\textsuperscript{22 1,30 1}

**Side-to-Side Anastomosis**

After the strangulated segment of small intestine is resected, the jejunum is transected and oversewn as for the ileum. The jejunum is attached to the selected area on the wall of the cecum (see “End-to-Side Anastomosis,” just previously) with interrupted sutures of 3-0 PDS at the oversewn end and 10 to 12 cm proximal to this point (see Fig. 35-25). Either a hand-sewn side-to-side method, GIA stapling instruments, or the cutting thread or saw technique\textsuperscript{297,302} can be used. A saw technique (with steel wire protected in catheters) can effectively achieve a side-to-side anastomosis and reduces contamination more than the stapling method but without the cost.\textsuperscript{302} The oversewn end of the jejunum should not extend beyond the stoma or a stagnant loop will form, and it should be directed toward the cecal base (Fig. 35-26). A stabilizing suture line between cecum and jejunum proximal to the stoma is optional.\textsuperscript{195} If the ileum is obstructed by a tumor, muscular hypertrophy, or chronic intussusception, an incomplete bypass can be used.\textsuperscript{80}

The colon of horses with small intestinal strangulation is usually tightly contracted around dehydrated contents, although it is not truly impacted. Removal of these contents\textsuperscript{303} should eliminate some downstream resistance and provide a more favorable pressure gradient for emptying of the small intestine into the cecum in horses with ileocecal or jejunoocecal anastomoses.

**Jejunoileal Anastomosis**

Jejunoileal anastomosis is an alternative to jejunocecal anastomosis (if sufficient ileum is available) and can be performed more quickly because fewer steps are required. It also eliminates potential problems with jejunocecostomy related to bypassing the ileocecal valve.\textsuperscript{300} This anastomosis has a tendency to obstruct and does not function as consistently as a jejunojejunostomy.\textsuperscript{195} However, this anastomosis functioned very well in a recent retrospective study.\textsuperscript{304} The two-layer anastomosis used, with a simple-continuous pattern in the mucosa and a simple-continuous pattern in the seromuscular layer, eliminated the problem of luminal cuff formation with inverting patterns,\textsuperscript{285} and this could explain the lack of obstruction.\textsuperscript{304}

**Surgery of the Duodenum and Duodenal Bypass**

Access to duodenum through a ventral median celiotomy is considerably easier in a foal than in an adult horse.\textsuperscript{94,141} The abdominal incision should be extended to the xiphoid cartilage, and a J-shaped incision is required in an adult horse.\textsuperscript{141} In addition, the table should be tilted to elevate the front end of an adult horse.\textsuperscript{141} Access can be improved by retraction, packing of the abdomen with saline-soaked towels, and suction to remove some unavoidable contamination.\textsuperscript{140}

Pyloric stenosis has been successfully corrected by pyloromyotomy, Heineke-Mikulicz pyloroplasty, gastrojejunostomy, or gastroduodenostomy.\textsuperscript{94,140,141} For a side-to-side gastroduodenostomy, a hand-sutured anastomosis is preferred over the GIA instrument,\textsuperscript{94,140,141} because stapled incision edges can heal together at the commissures of the stoma and cause stomal occlusion.\textsuperscript{94} Additionally, stapling instruments are difficult to use in the limited space.\textsuperscript{94} In one foal, a focal duodenal stricture was corrected by transverse closure of a full-thickness longitudinal incision that spanned the lesion.\textsuperscript{305} Choledochojejunostomy and duodenoojejunostomy have been used successfully in foals with obstruction of the common bile duct and duodenum at the level of the hepatopancreatic ampulla.\textsuperscript{94}

A duodenoojejunostomy can be used to bypass a duodenal stricture beyond the hepatopancreatic ampulla.\textsuperscript{27} A side-to-side gastrojejunostomy is used to bypass an extensive duodenal lesion and has been used in an adult horse with
proximal enteritis. A side-to-side jejunojejunostomy is performed distal to bypass procedures to prevent intestinal contents from stagnating in the blind loop between the obstruction and the stoma. The contents of this loop can pass aborally through this stoma, without entering the stomach.

In protracted cases of DPJ that do not respond to appropriate medical therapy, bypass procedures have been developed to drain the affected segment of small intestine into more normal distal segments, so that the large volumes of fluids can be reclaimed by intestinal absorption. In one method, a temporary duodenocoeostomy is performed through a 25- to 30-cm-long incision between the 17th and 18th ribs to approach the duodenum before it turns through its caudal flexure behind the base of the cecum. Adjacent portions of duodenum and cecum are joined by the “cutting thread” technique, which creates a stoma 2 cm in diameter. The goal is to allow the distended duodenum to drain into the cecum, with spontaneous closure of the fistula when the condition has resolved. A carbohydrate absorption test can be used during the recovery stage to determine if the stoma has healed spontaneously. For horses with DPJ, a duodenocecostomy through a ventral midline celiotomy is an alternative procedure that is effective in reducing gastric distention and reflux. An adult horse that had a gastrojejunostomy for DPJ became lethargic for 1 to 2 weeks after a grain diet, suggesting that it had developed the “dumping syndrome,” a metabolic consequence of rapid influx of gastric contents into the jejunum. Although this horse did well for a follow-up period of 8 years after gastrojejunostomy, it had trouble maintaining body weight for the first year after surgery.

Duodenal impactions can be treated successfully with massage of the intestinal contents into the stomach for removal by gastroscopy, or into the jejunum for manual disruption or removal by enterotomy. Failure of these methods can be followed by enterotomy through an incision in the dorsal paralumbar space, 3 cm caudal to the 18th rib. Location of this incision over the duodenal obstruction could be guided with some precision by ultrasound.

Small Intestinal Enterotomy
A longitudinal enterotomy on the antimesenteric surface of the small intestine can be required for removal of impactions with food components, foreign material, or ascarids (see Fig. 35-5), or to empty a segment of distended bowel to facilitate reduction of a strangulation in the epiploic foramen. An exception is ileal impaction with digesta, such as coastal Bermuda grass hay, which can be managed by other means (see earlier). Methods to prevent adherence of intestinal contents to the serosa around the incision include constant lavage of the bowel with warm saline or precoating the proposed enterotomy site with sodium carboxymethylcellulose. The enterotomy can be closed with a single layer (Lembert or Cushing pattern) using 2-0 PDS on a taper needle, or in two layers, such as a simple-continuous pattern in the mucosa followed by an inverting pattern. Advantages of the Cushing pattern for the final row are that less suture material is exposed to the peritoneal cavity, and there is minimal inversion. Any closure method should minimize lumen reduction and risk for adhesions.

An enterotomy is indicated to a lesser extent in small intestinal surgery than in colon surgery, and it should be avoided if possible and if other options are available, because the resulting closure could be a focus for adhesion formation. For example, viability can be assessed by seromuscular changes without need for mucosal inspection (see earlier). Extensive strangulating lesions can be corrected without removing fluid contents, although gas can be removed through an 18-gauge needle tunneled beneath the seromuscular layer and connected to a suction device. The tunnel stuggers puncture sites in the different layers so suture closure is unnecessary. A focal impaction with dehydrated intestinal contents can be softened by injection of saline through an 18-gauge needle into its substance or by mixing it with more proximal liquid contents. If a resection is not indicated, distended small intestine can be decompressed by massaging contents into the cecum, from which they can be removed by typhlotomy.

AFTERCARE FOR SMALL INTESTINAL SURGERY
Routine use of an indwelling nasogastric tube does not ensure against gastric rupture in horses and possibly contributes in some way to the secretory component of postoperative ileus. Therefore, decompression of the stomach is indicated only by clinical findings, such as pain and increased heart rate. I do not use an indwelling tube. Most horses can be offered a small handful of good-quality hay within 18 to 24 hours after surgery. This can be repeated at 3- to 4-hour intervals and the amount increased slowly to a full ration within 3 to 4 days. The refeeding process requires great care and close observation, but it can stimulate return of intestinal function. Early feeding is very well tolerated in horses with jejunojejunostomy. Broad-spectrum antibiotics and flunixin meglumine are administered before surgery and continued for 3 days afterward. Intravenous fluids are administered at 2 L/hr to a 450-kg horse for the initial 12 hours after surgery; the rate is subsequently adjusted for changes in packed cell volume and total plasma protein (see Chapters 3 and 39). Prokinetic drugs are used almost routinely by some surgeons or as needed by others.

REPEAT CELIOTOMY
Repeat celiotomy is a life-saving procedure and can be required for 12% to 27% of small intestinal diseases and for 4% to 12.5% of all colic surgeries. The need for repeat celiotomy is far greater after small intestinal surgery than after large intestinal surgery, and it is greater after jejunocecostomy than after jejunojejunostomy. Although making the distinction between postoperative ileus and mechanical obstruction from anastomotic impaction, ischemia, adhesions, or others can be difficult, horses with mechanical obstruction usually demonstrate a greater degree of pain and have a progressive increase in heart rate. The median time to relaparotomy in one study was 48 hours, with 67% of horses undergoing surgery within 72 hours of the first procedure.
Two important disadvantages of a second abdominal exploratory intervention are the risk for incisional infection and the expense; however, the benefits of this procedure can outweigh the risks and disadvantages in most cases, including prompt termination of hopeless cases and salvage of others with treatable lesions. Survival after a repeat celiotomy ranges from 36% to 56.4% and can be as low as 20% on a long-term basis. However, in one study, 74% of horses that were recovered after a second celiotomy were alive at 1 year after the second surgery.

COMPLICATIONS AND PITFALLS

The most common complications of small intestinal surgery in the horse are anastomotic obstructions (Fig. 35-27), adhesions, and postoperative ileus (POI). The clinical distinction between these three complications is difficult, and each can contribute to the pathogenesis of the other. The first two cause mechanical obstruction and are associated with greater and more persistent signs of abdominal pain than with POI. Technical errors are not well tolerated in small intestinal surgery in horses and can account for many complications. In a recent study of 74 horses that recovered from general anesthesia after small intestinal surgery, technical errors and errors in judgment were responsible for 8 of 14 repeat celiotomies (57%) and for 7 of 11 deaths during hospitalization (64%).

Anastomotic Obstruction

Mechanical obstruction of the anastomosis can be caused by impaction, hematoma, constriction, excessive shortening of the mesentery, and other errors in technique. Prolonged obstruction of an anastomosis can lead to adhesion formation (see Fig. 35-27). Stomas of marginal size are prone to obstruction because they are further reduced by post-anastomotic edema. Thereafter, the stoma reduces in size for up to 3 weeks because of wound contraction. Small intestinal volvulus may develop in distended jejunum and at points of small intestinal fixation, such as at a jejunocecal anastomosis. Risk of this complication is increased in a jejunocecal anastomosis by failure to decompress intestine during surgery and by placement of the jejunum toward the apex of the cecum, which twists the jejunum 180 degrees. Intussusception of the anastomosis has been reported in horses and ponies after functional end-to-end anastomosis, hand-sewn anastomosis, and inverting closure of a transverse enterotomy.

Jejunocecal and ileocecal anastomoses are usually associated with more postoperative complications than jejuno-jejunostomy. This difference can be explained by the bypass of the ileocecal valve and by the creation of a sharp transition between intestinal segments of dissimilar functions. The jejunum must overcome intracecal pressure to empty, without the coordinating mechanism of the ileum and ileocecal valve. Another factor that could contribute to postoperative complications is the presence of adhesions to a devitalized ileal stump and mesentery. In addition, with a jejunocecostomy, all the remaining small intestine was subjected to prestenotic distention that could delay return of function, whereas only a portion of the remaining intestine was subjected to dissection with jejunojejunostomy.

Postoperative Ileus

Postoperative ileus has a reported prevalence that varies from 10% to 55.6% and a mortality rate of 13% to 86%, accounting for 9% to 43% of all deaths after small intestinal surgery. In one study on small intestinal surgery, no horse developed POI after jejunojejunostomy, whereas 20% of horses that had had a jejunocecostomy did. Although prokinetic drugs can be used for treatment (see Chapter 39), the role of mechanical obstruction must not be overlooked, because this delays the use of repeat laparotomy. Many horses with postoperative ileus will benefit from decompression at a second surgery. Pelvic flexure enterotomy (see Chapter 36) may reduce the risk for POI, possibly by reducing resistance to ileal emptying and by decreasing compression of hypomotile intestine by a full colon.

Adhesions

Adhesions have been documented in 6% to 26% of horses after small intestinal surgery, with a marked decline in prevalence over time. Adhesions usually cause signs of intestinal obstruction in the first 2 months after surgery, but adhesion-related obstruction can arise at any time. Although foals are considered to be especially prone, adhesion formation in juvenile Thoroughbreds after surgery for lesions of all parts of the gastrointestinal tract has been reported at 8%, similar to the percentage reported for adult horses. Foals of 15 days to 6 months seem more likely than weanlings and yearlings to develop adhesions and require multiple surgeries. Factors that could contribute to adhesions are postoperative ileus, ischemia, foreign material, serosal abrasion by towels, excessive handling of bowel, and use of large suture material.

Figure 35-27. Effects of prolonged (5 days) anastomotic obstruction caused by excessive shortening of the mesentery at the anastomosis. Note the hemorrhage in the proximal bowel to the right and the fibrinous adhesions in the loops in the right foreground.
**Short Bowel Syndrome**

Short bowel syndrome has been documented in horses after extensive small intestinal resection. According to one study, resection of 60% or more of small intestine can lead to malabsorption. A subsequent study demonstrated that resection of 70% of the small intestine of ponies is well tolerated. Clinical experience supports this conclusion, although the limit for resection can vary among horses, and residual bowel can compensate over time. Mural congestion caused by venous strangulation can increase the length of the affected segment of small intestine by as much as 36%, so some correction for an increase in length after strangulation is needed to avoid an overly pessimistic estimate of the risk for short bowel syndrome. A correction factor that would apply to different severities of strangulation encountered in clinical cases is difficult to establish, and therefore assessment of the remaining length of small intestine could be a more meaningful predictor of postoperative absorptive capacity. A minimal length of 4.5 m (15 feet) of remaining small intestine would be adequate in an adult horse, which approximates what would be left after resection of 75%. Removal of longer segments does not appear to be well tolerated, although one 450-kg horse left with 3.7 m (12.3 feet) did not develop short bowel syndrome, which is evidence of a tremendous individual variation.

Other potential complications of extensive small intestinal resection are liver disease and anorexia. Bypass of the ileocecal junction by jejunocecal anastomosis without resection can allow cecal bacteria to seed the small intestine and cause an abnormal xylose absorption test in ponies, which is apparently not the case in horses. Although based on findings from laboratory animals, postoperative dietary recommendations that may apply to horses with short bowel syndrome include complex nutrients as potent stimulants of intestinal adaptation, and fiber to increase colonic production of short-chain fatty acids (see Chapter 6). Carbohydrates should be fed sparingly, as they are more likely than fats and proteins to induce osmotic diarrhea.

**Miscellaneous**

Anastomotic dehiscence and peritonitis are rare in most studies, but they were a leading cause of death when staples were used for all small intestinal anastomoses in horses. Failure to effectively ligate mesenteric vessels can lead to postoperative hemorrhage. Occlusion or kinking of vessels or postoperative thrombosis of mesenteric vessels for unknown reasons can cause Anastomotic necrosis. Mesenteric rents at sites remote to the anastomosis have been described as causes of recurrent small intestinal strangulation and death, years after the original surgery. Other complications include pyrexia, jugular vein thrombosis, long-bone fracture, cecal impaction, myositis, endotoxemia, gastric ulceration, recurrent colic, incisional infections, diarrhea, and pulmonary aspergillosis. Some horses have concurrent large intestinal displacement or develop large intestinal distention or impaction after surgery.

**PROGNOSIS**

At least six studies reported survival rates to discharge of 80% to 88% in horses that had surgery of the small intestine and were allowed to recover from anesthesia. Advances in management and early referral are important determinants of survival, and of the severity of endotoxemia and other complications, such as jugular thrombosis, postoperative ileus, and wound infection. In 115 horses with small intestinal volvulus, nonsurvivors had higher heart rates, longer capillary refill time, greater hemoconcentration, and more exudation of cells and protein into peritoneal fluid at admission than survivors. After small intestinal resection, postoperative factors that were associated with nonsurvival were ileus, heart rate greater than 60 beats per minute at 24 hours, and repeat celiotomy. In 143 horses with entrapment in the epiploic foramen, survival was 75.6% if surgery was performed within 8 hours from the onset of colic, compared with 45.1% survival in horses that underwent surgery 12 hours or more after onset. Multiple logistic analysis demonstrated that duration of surgery was not a factor associated with short-term survival in horses that had small intestinal resection, in contrast to its negative effect on survival when all types of colic are considered. In one study on small intestinal surgery, surgeon experience was the only factor that appeared to influence survival significantly.

In horses with colic from small intestinal disease, survival after simple obstruction is not significantly different from survival after strangulation obstruction. Although length of resection does not appear to influence outcome, a trend toward lower survival has been reported after resection of greater than 2 m of intestine. Another study found an approximately linear inverse relationship between survival and intestinal resection length. The length of bowel strangulated in the epiploic foramen was longer in nonsurvivors than survivors in another study. Lesions that appear to have an adverse influence on survival are strangulation in the epiploic foramen and in mesenteric rents, and ascarid impactions. Prognosis tends to be better after a jejunojejunostomy than after a jejunocecostomy or ileocecostomy, and jejunocecostomy is associated with increased likelihood of postoperative abdominal pain and repeat celiotomy. Volvulus at the anastomosis, infarcted jejunum at the anastomosis, and technical errors accounted for most complications from jejunocecostomy in one study, whereas problems with the ileal stump caused 47% of surgery-related complications in another. However, survivals after jejunojejunostomy and jejunocecostomy become similar over the long term. Survival after jejunocecostomy or ileocecostomy without resection is better than after the same procedures with resection. Correction by reduction, bypass, enterotomy, or “kneading” has a better prognosis than after resection and anastomosis.

In a report on foals with surgical colic, only 10% of those younger than 14 days survived to maturity compared with 45.8% of foals 15 to 150 days old. In one study, 59% of...
foals that had surgery for colic survived to discharge, with 25% being euthanized while under anesthesia. The survival for foals that had a small intestinal lesion (46%) was worse than for those with large intestinal lesions (80%). Survival in foals is also greater after nonstrangulating lesions or simple obstruction than after strangulating obstruction.

The pattern of survival after surgery for horses with small and large intestinal colics follows a triphasic pattern. Most deaths occur during the first 10 postoperative days, with 69% during the first 100 days after surgery and a slower decline in death rate after that. A study on horses that had small intestinal surgery confirmed this observation and also demonstrated that the risk for death from surgery-related problems diminishes markedly after 12 months.

CECUM

Anatomy and Physiology

The cecum is positioned between the small intestine and the large colon and located primarily on the right side of the abdomen. It is a large cul-de-sac with an average length of 1.25 m and an average capacity of 30 L. It has a comma-shaped appearance and is divided into three parts—the base, body, and apex (Fig. 36-1). The base, which is the most dorsal part, is positioned in the right iliac and sublumbar region. It has a greater curvature dorsally and lesser curvature ventrally. It extends cranially to the 14th or 15th rib, forming a blind end pointing ventrally. A transverse fold, arising from the floor of the cecal base cranial to the ileocecal junction, divides the base into a cranial and a caudal portion. The cranial part of the base is developmentally part of the ascending colon and is called the cupula. The cranial and caudal parts of the cecal base appear to function separately. The body of the cecum travels cranioventrally from the cecal base. Caudally, it lies against the right flank moving to a slightly more medial position as it extends cranial along the ventral body wall, narrowing toward the cecal apex, which is situated between the right and left ventral colon approximately 20 cm caudal to the xiphoid cartilage. The cecal base is attached dorsally to the ventral surface of the right kidney, to the right lobe of the liver, and left ventral colon approximately 20 cm caudal to the xiphoid cartilage. It has a comma-shaped appearance and is divided into three parts—the base, body, and apex (Fig. 36-1). The base, which is the most dorsal part, is positioned in the right iliac and sublumbar region. It has a greater curvature dorsally and lesser curvature ventrally. It extends cranially to the 14th or 15th rib, forming a blind end pointing ventrally. A transverse fold, arising from the floor of the cecal base cranial to the ileocecal junction, divides the base into a cranial and a caudal portion. The cranial part of the base is developmentally part of the ascending colon and is called the cupula. The cranial and caudal parts of the cecal base appear to function separately. The body of the cecum travels cranioventrally from the cecal base. Caudally, it lies against the right flank moving to a slightly more medial position as it extends cranial along the ventral body wall, narrowing toward the cecal apex, which is situated between the right and left ventral colon approximately 20 cm caudal to the xiphoid cartilage. The cecal base is attached dorsally to the ventral surface of the right kidney, to the right lobe of the liver, and left ventral colon approximately 20 cm caudal to the xiphoid cartilage. It has a comma-shaped appearance and is divided into three parts—the base, body, and apex (Fig. 36-1). The base, which is the most dorsal part, is positioned in the right iliac and sublumbar region. It has a greater curvature dorsally and lesser curvature ventrally. It extends cranially to the 14th or 15th rib, forming a blind end pointing ventrally. A transverse fold, arising from the floor of the cecal base cranial to the ileocecal junction, divides the base into a cranial and a caudal portion. The cranial part of the base is developmentally part of the ascending colon and is called the cupula. The cranial and caudal parts of the cecal base appear to function separately. The body of the cecum travels cranioventrally from the cecal base. Caudally, it lies against the right flank moving to a slightly more medial position as it extends cranial along the ventral body wall, narrowing toward the cecal apex, which is situated between the right and left ventral colon approximately 20 cm caudal to the xiphoid cartilage. The cecal base is attached dorsally to the ventral surface of the right kidney, to the right lobe of the pancreas, and to a part of the abdominal wall caudal to these structures. The cecal base is attached medially to the transverse colon and the root of the mesentery from which the vascular supply reaches the cecum.

The body of the cecum has four longitudinal bands (teniae) located on the dorsal, ventral, medial, and lateral surfaces. The dorsal and medial bands end at the cecal apex. The ventral band usually joins the medial band near the cecal apex, and the lateral band may extend to the apex or fade out before reaching the apex. The ileocecal fold runs from the antimesenteric border of the ileum to the dorsal cecal band. The cecocolic fold (ligament) runs from the lateral cecal band to the lateral free band of the right ventral colon.

The cecal blood supply derives from the cecal artery, a branch of the ileocolic artery. The cecal artery divides into the medial and lateral cecal arteries, which run with the corresponding veins in the medial and lateral cecal bands, respectively. The medial cecal artery is the major vascular supply to the cecal apex. The cecum is thought to be at risk for thromboembolic disease, since both cecal arteries arise from a single vessel without collateral circulation, and since the lateral and medial cecal arteries have minimal mixing of...

CECUM
Anatomy and Physiology

The cecum is positioned between the small intestine and the large colon and located primarily on the right side of the abdomen. It is a large cul-de-sac with an average length of 1.25 m and an average capacity of 30 L. It has a comma-shaped appearance and is divided into three parts—the base, body, and apex (Fig. 36-1). The base, which is the most dorsal part, is positioned in the right iliac and sublumbar region. It has a greater curvature dorsally and lesser curvature ventrally. It extends cranially to the 14th or 15th rib, forming a blind end pointing ventrally. A transverse fold, arising from the floor of the cecal base cranial to the ileocecal junction, divides the base into a cranial and a caudal portion. The cranial part of the base is developmentally part of the ascending colon and is called the cupula. The cranial and caudal parts of the cecal base appear to function separately. The body of the cecum travels cranioventrally from the cecal base. Caudally, it lies against the right flank moving to a slightly more medial position as it extends cranially along the ventral body wall, narrowing toward the cecal apex, which is situated between the right and left ventral colon approximately 20 cm caudal to the xiphoid cartilage. The cecal base is attached dorsally to the ventral surface of the right kidney, to the right lobe of the pancreas, and to a part of the abdominal wall caudal to these structures. The cecal base is attached medially to the transverse colon and the root of the mesentery from which the vascular supply reaches the cecum.

The body of the cecum has four longitudinal bands (teniae) located on the dorsal, ventral, medial, and lateral surfaces. The dorsal and medial bands end at the cecal apex. The ventral band usually joins the medial band near the cecal apex, and the lateral band may extend to the apex or fade out before reaching the apex. The ileocecal fold runs from the antimesenteric border of the ileum to the dorsal cecal band. The cecocolic fold (ligament) runs from the lateral cecal band to the lateral free band of the right ventral colon.

The cecal blood supply derives from the cecal artery, a branch of the ileocolic artery. The cecocolic artery divides into the medial and lateral cecal arteries, which run with the corresponding veins in the medial and lateral cecal bands, respectively. The medial cecal artery is the major vascular supply to the cecal apex. The cecum is thought to be at risk for thromboembolic disease, since both cecal arteries arise from a single vessel without collateral circulation, and since the lateral and medial cecal arteries have minimal mixing of
their two circulations. However, microvascular studies indicate that there is a cecal rete arising from each of the cecal arteries that supplies an extensive submucosal plexus and that may provide an alternative blood supply in the event of a cecal embolus (Fig. 36-2).

The ileocecal orifice is located in the lesser curvature of the cecal base approximately 5 to 7 cm to the right of the median plane and at the level of the first or second lumbar vertebra. The end of the ileum is partly telescoped into the cecum, which positions the ileal orifice in an elevation of an annular fold of mucous membrane. The annular fold contains a network of veins, which can distend the annular fold when engorged. In this way, the ileocecal orifice is narrowed, preventing reflux of cecal contents back into the ileum. The lack of this functional sphincter may contribute to cecal reflux into the small intestine after a jejunoceco-stomy. The cecocolic orifice is located distal to the ileocecal orifice. Because the cranial cecal base curves ventrally and caudally, the cecocolic orifice is positioned caudal and lateral to the ileocecal orifice (see Fig. 36-1, B). It lies between two folds of tissue, which form the cecocolic valve. There is no sphincter at the cecocolic orifice.

The two primary physiologic functions of the cecum (as well as of the large colon) are to absorb electrolytes and water and to serve as a site of microbial digestion. The large intestine of a 160-kg pony reabsorbs a total of approximately 30 L of water a day, a volume equivalent to its extracellular space. The cecum appears to be the site of greatest quantitative net water absorption (Fig. 36-3). In an experimental model in ponies, the cecum demonstrated a net transmucosal influx of water during the first 2 hours after a meal, followed by a net absorption of approximately 600 to 800 mL/hr during the next 10 hours between meals. Net increases in daily absorption of water from the ventral and small colon can compensate for decreased cecal water absorption. Microbial digestion is the other important physiologic function of the cecum. A significant amount of soluble and most of the insoluble (e.g., cellulose, hemicellulose) dietary carbohydrate is digested by microbial enzymes in the cecum (and large colon) with production of organic acids (volatile fatty acids). The marked decrease in bicarbonate in the cecum is because of the buffering effect of the organic acids. Although osmotic changes in organic acid (or volatile fatty acid) production has been speculated to control net water movement, sodium transport is probably more important.
The cecum is relatively rapid compared with that in the large intestine of a 70-kg man and a 160-kg pony. Both species absorb approximately 90% of ileal outflow, but in a pony, this represents approximately 30 L/day. The volume is roughly equivalent to the animal’s extracellular fluid volume. Note that the cecum of the pony has the greatest net water absorption. (Redrawn from Argenzio RA, Lowe JE, Prickard DW, et al: Digesta passage and water exchange in equine large intestine, Am J Physiol 1974;226:1035.)

Cecal Motility

The transit time for liquid and particulate markers through the large intestine of a 70-kg man and a 160-kg pony. Both species absorb approximately 90% of ileal outflow, but in a pony, this represents approximately 30 L/day. The volume is roughly equivalent to the animal’s extracellular fluid volume. Note that the cecum of the pony has the greatest net water absorption. (Redrawn from Argenzio RA, Lowe JE, Prickard DW, et al: Digesta passage and water exchange in equine large intestine, Am J Physiol 1974;226:1035.)

Figure 36-3. Net water movement through the large intestine of a 70-kg man and a 160-kg pony. Both species absorb approximately 90% of ileal outflow, but in a pony, this represents approximately 30 L/day. The volume is roughly equivalent to the animal’s extracellular fluid volume. Note that the cecum of the pony has the greatest net water absorption. (Redrawn from Argenzio RA, Lowe JE, Prickard DW, et al: Digesta passage and water exchange in equine large intestine, Am J Physiol 1974;226:1035.)

Cecal Motility

The transit time for liquid and particulate markers through the cecum is relatively rapid compared with that in the large colon. There does not appear to be any retrograde movement of ingesta through either the ileocecal or the cecocolic orifice. Several studies have described normal cecal motility by examining cecal myoelectric activity patterns. Ingesta enters the cecum from the ileocecal orifice propelled by the migrating action potential complex, a rapidly progressive electrical event extending from the ileum to the cecum. In the cecum, four different patterns of activity have been characterized. There are associated with mixing of cecal ingesta: pattern I begins at the cecal apex and is conducted to the cranial base, and patterns II and III begin at the caudal and cranial cecal base, respectively, and are conducted to the cecal apex.

Pattern IV, a progressive pattern, begins at the cecal apex and is conducted through the cecal base and cecocolic orifice and into the right ventral colon (RVC). Pattern IV occurs once every 3 minutes in the fed horse, is associated with a loud distinctive “rush” of digesta (heard on auscultation), and is probably responsible for the transit of digesta from the cecum to the RVC. In endoscopic studies of cecal emptying, ingesta was seen to move from the body up to the cranial aspect of the cecal base (cupula), which was separated from the caudal base by a ring of constriction. The cupula then contracted and the cecocolic orifice was elevated and opened, allowing ingesta to flow into the RVC. In the RVC, both aborally directed propulsive spike bursts and orally directed retropulsive spike bursts were seen. The orally directed spike bursts may allow the RVC to function as a reservoir. The oral spike bursts were not propagated onto the cecum. An electrical pacemaker region is thought to be located near the cecal apex. There is also indication of possible myoelectric coupling between the ileum, cecum, and RVC. Abnormal cecal motility is thought to contribute to several cecal problems, most notably cecal impaction caused by cecal dysfunction.

Cecal Impaction

Pathogenesis

The most common pathologic condition of the cecum is cecal impaction, and it accounts for between 40% and 55% of cecal disease, 5% of all intestinal impactions, and 2% of all referral colics. Fatalities as high as 43% have been reported, primarily because of perforation or rupture. The etiology of cecal impaction is most likely multifactorial. Suggested predisposing factors include poor dentition, feeding of poor-quality roughage, decreased water intake, parturition, and parasite-induced thromboembolism. Tapeworms (Anoplocephala perfoliata) located at the cecocolic orifice have been associated with cecal impaction and perforation, possibly as the result of disruption of motility. In one study, Arabian, Appaloosa, and Morgan horses, as well as horses older than 15 years, were at an increased risk for developing cecal impactions. In our experience, horses from regions where coastal Bermuda grass hay is the predominant diet are also at an increased risk.

Another predisposing factor for cecal impaction, which may lead to cecal perforation, is hospitalization or prior surgery (within the previous 5 days). Often these horses are hospitalized or have surgery for reasons not related to the gastrointestinal tract, such as elective arthroscopy. Some of these impactions may be related to a motility dysfunction. During and after general anesthesia, motility of the gastrointestinal tract is disrupted, with the cecum taking the longest time to return to normal function. Use of nonsteroidal anti-inflammatory drugs (NSAIDs) and lack of exercise have also been associated with the development of cecal impaction or rupture in these cases.
association of NSAIDs with cecal rupture has been attributed to masking of gastrointestinal pain associated with cecal impaction, exacerbation of existing ulceration associated with concurrent disease, and primary ulcer development.4,19,24,39 There is also a group of horses that develop cecal “impactions” that do not appear to have a mechanical obstruction. In these horses, the accumulated ingesta is of normal or often fluid consistency instead of the firm, dry, compacted ingesta typically associated with feed impactions. A functional motility obstruction has been suggested in this group of horses. A disruption in the progressive motility pattern, which starts at the cecal body and propagates aborally to the cecal base and into the right ventral colon, would lead to accumulation of ingesta in the cecum.7,8 Although altered blood flow secondary to parasitic damage, dietary changes, and other clinical conditions have been hypothesized to disrupt the cecal pacemaker located at the cecal apex and to result in interruption of progressive motility, no predisposing cause can be found in many of these cases.

Chronic recurrent cecal impaction has also been associated with hypertrophy of the muscle layers in the cecal base or body.40 The muscular hypertrophy is thought to result from chronic uncoordinated hypercontractility because of neuronal deficits in the myenteric plexus of the cecal base.40,41 Ingesta accumulates in the cecum as a result of failure of the motility patterns to move ingesta from the cecum into the RVC. These horses have chronic weight loss with mild signs of colic. To our knowledge, this type of cecal disease has not been recognized in the United States.

Clinical Signs and Diagnosis

Often, horses with cecal impaction show only mild signs of pain, with intermittent periods of increased severity, that may continue for several days to several weeks.19,23,42,44 The mild signs of colic include lying down, looking at the flank, decreased appetite, and depression. The heart rate is often normal to slightly elevated. Borborygmi are decreased, and feces may be soft with decreased production. Because gas, fluid, and some ingesta may pass through the cecum over the impaction, the small intestine proximal to the cecum is usually not distended. Although some horses may be presented with or may develop moderate to severe pain as the impaction progressively worsens, some affected horses remain relatively comfortable as the cecum becomes tightly distended. Horses with cecal impaction may be presented with cecal rupture with no history of significant abdominal pain.19,23,44 There are reports of horses with cecal impaction deteriorating so rapidly, even when being monitored in a hospital environment, that surgical intervention before cecal rupture was not possible.23,24,34 Laboratory evaluation is often normal in horses with cecal impactions. Although changes in peritoneal fluid may help in determining when and if surgical intervention should be performed, they are not always a sensitive predictor of cecal deterioration and may occur too late to be of any value in the decision-making process.39,23,24

The diagnosis is confirmed by rectal palpation in most cases.1,2,3,18-21 The first indication of a cecal impaction may be increased tension in the ventral cecal band. As the impaction enlarges, the cecal body begins to fill and the sacculations in the cecal body and a rounded cecal base are palpable. With increasing filling, the sacculations disappear and a large distended structure can be felt filling the right side of the abdomen. Because the cecum is attached dorsally to the body wall, the examiner is not able to pass a hand dorsally over the impaction.39 This may help differentiate a cecal impaction from a large colon impaction. However, rectal palpation in some cases is not definitive in distinguishing between a distended cecum and a distended colon.26 Additionally, some horses have cecal impaction involving only the cupula. Since the cupula of the cecum lies more cranial than the body, these can be missed on rectal palpation.40

Primarily on the basis of rectal palpation findings, cecal impactions have been divided into two types of obstruction.23,38 One type has firm, dry, or doughy ingesta at the base or body of the cecum. The mass can be indented with the fingers on rectal palpation, and the cecal wall does not feel thickened. Peritoneal fluid is usually normal in these horses. These cases are thought to include the mechanical obstructions and will be referred to as type 1 cecal impactions. In the other type of cecal impaction, referred to here as type 2 cecal impactions, the cecum is tightly distended with gas and ingesta of normal or fluid consistency. These have been described as cecal dysfunction.23,38 These horses may have an increased level of pain and an increased heart rate compared with type 1 cecal impactions. They may also show signs of endotoxemia. The cecal wall is usually tightly stretched and may feel thickened. Peritoneal fluid may have elevated protein, and as the disease progresses it becomes serosanguineous. At surgery, the cecal wall appears thickened and hyperemic, and it has decreased motility.23,38 Although this categorization may be helpful in selecting a treatment modality (see “Treatment,” next), it is not without limitations. First, it can be difficult to place a horse accurately into one of the two categories, even with physical, rectal, laboratory, and surgical findings. Second, although the progression of the disease and the response to treatment modalities may be more similar between horses within a group than between horses in different groups, clinically there are significant exceptions.

Treatment

The treatment of cecal impactions is quite controversial. Some reports suggest that cecal impactions can routinely be successfully treated with medical therapy, whereas other reports recommend surgical intervention.4 To differentiate horses that will respond to medical therapy from those that will not, attempts have been made to correlate the characteristics of the impaction (the nature of the material in the cecum) with the response to medical therapy. Type 1 cecal impactions, thought to be mechanical obstructions from impacted ingesta, should be more likely to respond to medical therapy.23,38 Type 2 cecal impactions, thought to be caused by a cecal motility dysfunction, should be less likely to respond to medical therapy and so be more likely to require surgical intervention. Although type 1 cecal impactions can initially be treated with medical therapy, some may not respond. Since these horses may not show

*References 3, 23, 24, 38, 39, 43.
much pain at any stage of the disease, they should be carefully monitored by rectal examination to determine which ones are not responding.

Another area of controversy is associated with the timing of performing a surgical bypass of the cecum. This question arose out of several retrospective studies that identified horses with recurrent cecal tympany or impaction after a prior typhlotomy without bypass had been performed to treat cecal impaction. The nature of the impaction has been used to help with this decision. Type 1 impactions should be more likely to respond to decompression only, whereas cecal dysfunction, the type 2 impactions, should be more likely to require a bypass. However, this has been questioned by some authors. In our opinion, cecal impactions that occur in the postanesthetic period can be treated medically if they are diagnosed prior to the cecum's becoming overdistended. However, it should be stressed that the clinical signs may be mild and their clinical significance underestimated. In a retrospective study of cecal perforation, 13 of 66 horses with cecal disease developed cecal perforation while in a hospital setting without having a prior diagnosis of cecal disease. All of these horses had some sort of painful condition, many related to a musculoskeletal condition. Seven of these 13 cases had general anesthesia several days prior to cecal perforation. Although these horses exhibited signs such as reduced fecal output and mild abdominal pain, the signs were not recognized as clinically significant prior to cecal perforation or sudden death. These horses were found to have a large and firm cecum filled with ingesta and an empty colon at necropsy. If surgery is required for decompression of postoperative cecal impactions, or if horses develop cecal impaction while hospitalized for other conditions, most cases will not need a bypass. The logic is that the dysfunction is temporary in nature and its safety of bethanechol and erythromycin for the treatment of cecal impaction are not known. Although separation into type 1 and type 2 cecal impactions provides some guidance in choosing which cases are more likely to respond to medical therapy, horses undergoing medical therapy for cecal impaction remain at risk for developing cecal rupture. Consequently, close monitoring of their physical status, including heart rate and level of pain, as well as transrectal monitoring of the impaction are imperative when treating any cecal impaction medically. Surgery should be considered if there is no improvement on rectal palpation during a 24- to 36-hour period, if there is any sign of systemic deterioration, if there is a significant increase in pain, or if the cecum feels tight enough to rupture.

The prognosis with medical therapy is difficult to assess from previous reports. One study reported a good prognosis for horses with cecal impactions treated with medical therapy when they lived longer than 24 hours after admission. However, horses that may have been treated medically initially and that developed cecal rupture before the 24 hours were not included in the medically treated group. Consequently, it is difficult to interpret the significance of the reported survival rate (89%) of medically treated cecal impactions. Nine of 10 horses (90%) were treated successfully medically in another study, where the majority of cases (21 of 31 treated) were managed surgically. In another study, medical therapy alone was unsuccessful in 12 out of 21 horses with cecal impaction. Poor results with medical therapy have been reported by other authors.

**MEDICAL THERAPY**

The goal of medical therapy in type 1 impactions is to soften the ingesta to allow cecal contractions to empty the cecal contents into the right ventral colon. Feed should be withheld and the horse started on intravenous fluid therapy. Oral laxatives administered by nasogastric tube may assist in softening the impaction. Mineral oil (5 to 10 mL/kg every 12 hours) is commonly used as a lubricant but may have difficulty penetrating the mass. Magnesium sulfate (1 mg/kg) is a saline laxative that exerts an osmotic effect, pulling water into the intestinal lumen. It can be administered once or twice a day for 2 to 3 days if the horse is well hydrated. Magnesium toxicity has been reported after the use of magnesium sulfate in dehydrated horses and in horses that have been treated with a combination magnesium sulfate and dicyclol sodium sulfosuccinate (DSS), which is thought to increase the absorption of magnesium. Psyllium hydrophilic mucilloid (1.0 kg every 6 to 8 hours) has also been recommended for treatment of cecal impactions. Because complete fasting causes cessation of cecal motility, stimulating motility by walking and limited controlled grazing may be beneficial. Analgesics such as flunixin meglumine (0.5 to 1.1 mg/kg IV every 12 hours) can be used if necessary for pain relief in both types of impactions. Caution should be exercised in using xylazine and butorphanol, since both drugs have been shown to decrease cecal contractile activity and their analgesic effect may inappropriately delay the decision for surgical intervention. There is no consensus on the use of prokinetics. Erythromycin, bethanechol, and neostigmine have all been shown to increase contractile activity in the normal cecum as stated previously. Given the apparent large force of drug-induced activity in the normal cecum, some authors do not recommend the use of neostigmine in horses with cecal impaction. The clinical efficacy and safety of bethanechol and erythromycin for the treatment of cecal impaction are not known.

**SURGICAL THERAPY**

The ventral midline celiotomy is the most common approach for surgical access to the cecum. Because the cecal base is firmly attached to the dorsal body wall, only the apex and a portion of the body of the cecum can be exteriorized. The entire base (including the cupula), a portion of the cecal body, and the cecocolic and ileocecal orifices will remain within the abdominal cavity. A right paracolic approach made through an 18th rib resection has been described for complete typhlectomy or enlargement of the cecocolic orifice in horses with cecal impaction associated with cecal hypertrophy. In Europe, enlargement of the cecocolic orifice has met with limited (50%) success in treating this particular type of cecal disease.
Surgical options are infusion of fluid with massage of cecal contents, typhlotomy with evacuation of cecal contents, and bypass procedures including cecocolic anastomosis, ileocolostomy, and jejunoileostomy. Poor to good results have been reported with infusion combined with massage. This technique has been of limited value in our experience. For type 1 impactions, the mass of ingesta is usually too large and too tightly packed for infusion and massage to be of significant benefit in breaking down the impaction. Type 2 impactions already contain a significant amount of fluid and so are not likely to respond to additional fluid infused to break them down. There is still controversy concerning the criteria to use in deciding when to perform a bypass procedure. As a general rule, horses fitting into the type 2 category should be considered candidates for a cecal bypass. Some authors state that if the cecal wall appears normal and has reflex motility, and if the ventral colon contains a normal amount of ingesta, the cecum is not bypassed, whereas if the cecal wall is thickened and hyperemic and has minimal motility after evacuation, and if the ventral colon is almost empty, suggesting a cecal motility problem, the cecum should be bypassed. These are valid guidelines, although there appear to be exceptions.

Typhlotomy: The preferred surgical approach for a typhlotomy is through a ventral midline celiotomy, although the procedure can be performed through a flank laparotomy in the standing animal. The cecum is usually quite large and tightly distended, sometimes making it difficult to exteriorize a sufficient portion of the apex to perform the typhlotomy. Extending the celiotomy incision improves the exposure. The cecum should be manipulated carefully with hands and arms placed around the body of the cecum, lifting the cecal body to allow exteriorization of the apex. Tilting the table, or tilting the horse slightly to the right side, can also facilitate exposure of the apex for the typhlotomy procedure. The exteriorized apex should be isolated from the sterile field over the side of the horse. Stay sutures can also facilitate exposure of the apex for the typhlotomy. The cecum and origin of the right ventral colon (RVC). (Redrawn from Ross MW, Tate LP, Donowick WJ)

Figure 36-4. The cecum and origin of the right ventral colon (RVC). The marked areas show the location of the cecocolic anastomosis, a surgical procedure useful for horses with recurrent cecal impaction. The anastomosis is performed between the lateral (A) and dorsal (B) cecal bands, and the lateral (C) and medial (D) free bands of the RVC. The cecocolic ligament (E) runs between the lateral cecal band and the lateral free band of the RVC. (Redrawn from Ross MW, Tate LP, Donowick WJ, et al: Cecocolic anastomosis for the surgical management of cecal impaction in horses, Vet Surg 1986;15;85.)
to reduce peritoneal and serosal contamination. For the stapling technique, stay sutures attaching the cecum and colon are placed at each end of the selected anastomosis site, approximately 20 cm apart. The seromuscular layer of the cecum and colon are apposed on one side of the intended stoma in a simple-continuous pattern using 2-0 polyglactin 910. Two small stab incisions are made on either side of the midpoint of the 20-cm suture line, one into the cecum and the other into the colon to allow insertion of the stapling instruments. The GIA-90 or ILA-100 stapling instrument is used twice, once orad and once aborad, taking care to overlap the staple lines, which makes a stoma between 15 and 20 cm in length (Fig. 36-5). The stab incisions are closed and the front side of the stapled seromuscular layer is oversewn. To reduce the possibility of internal hernia formation between the cecum and the colon, the seromuscular closures are continued dorsally to the level of the cecocolic ligament.

In one study, three of four horses survived after this technique. In another case series of 14 horses treated by CCA, the long-term survival (12 months) was 71%. However, 4 of the 10 long-term survivors experienced chronic, intermittent, mild abdominal pain thought to be associated with gaseous distention of the cecum. This was considered to be a result of failure of normal gas transit between the two organs, or reflux of gas from the colon into the cecum. Because of the number of horses continuing to experience postoperative problems related to the cecum after the CCA, alternative techniques that bypass the cecum have been recommended in horses with cecal impactions.

Jejunocolostomy or ileocolostomy: For cecal impactions arising from abnormal cecal motility or compromised outflow at the cecocolic orifice, procedures that bypass the cecum entirely have been recommended to prevent cecal tympany or the recurrence of cecal impaction. In these bypass procedures, an anastomosis is made between the ileum or jejunum and the right ventral colon. A partial bypass has been described in which the ileum is not transected. However, in an experimental study comparing a partial to a complete cecal bypass, the partial cecal bypass failed to decrease the size of the cecum or volume of ingesta in the cecum. Consequently, this was thought to be a risk for reimpaction and perforation. Additionally, intermittent colic with cecal distention has been reported after partial cecal bypass. The complete bypass, by taking the cecum out of the flow of ingesta, results in cecal atrophy and prevents postoperative cecal filling and rupture. For these reasons, the complete bypass is recommended over the partial bypass.

The cecum is approached through a ventral midline celiotomy and the cecal impaction evacuated through a typhlotomy. The ileal vascular arcade is double-ligated on both sides of the area of transection. The transection can be completed by hand, with the TA-90 stapling instrument positioned on the distal end and sharply transecting proximal to the instrument, or with a GIA-90 or ILA-100 that will cut between stapled proximal and distal ends. Doyen intestinal clamps are placed across the ileum oral and aboral to the line of transection for hand-sutured techniques. The proximal and distal ends of the hand-transected ileum are closed with a full-thickness continuous appositional or inverting pattern followed by a partial-thickness

Figure 36-5. The cecum and the origin of the right ventral colon are shown. A, Stay sutures attaching the cecum and colon are placed at each end of the selected anastomosis site, approximately 20 cm apart, and the seromuscular layer of the cecum and colon are apposed on one side of the intended stoma in a simple-continuous pattern. B, Two small stab incisions are made on either side of the midpoint of the 20-cm suture line, one into the cecum and the other into the colon, to allow insertion of the stapling instruments. The GIA-90 or ILA-100 stapling instrument is used twice, once orad and once aborad, taking care to overlap the staple lines, which makes a stoma between 15 and 20 cm in length. C, The stab incisions are closed and the front side of the stapled seromuscular layer is oversewn.
inverting pattern using an absorbable suture. All stapled ends should be oversewn with a partial-thickness inverting pattern. The proximal blind end of the ileum is directed orally, toward the base of the cecum, as it is positioned on the most proximal exteriorized portion of the right ventral colon between the lateral and medial free bands (Fig. 36-6). Stay sutures are placed 15 cm apart to attach the distal end of the ileum to the RVC. A Penrose drain is placed proximal on the ileum, and intestinal clamps placed on the RVC to minimize contamination during the anastomosis. Although a hand-sutured side-to-side anastomosis can be used, we prefer the use of intestinal stapling equipment to shorten surgery time and decrease contamination. Stab incisions are made in adjacent areas of the attached ileum and RVC. The arm of a GIA or ILA stapling instrument is inserted into one stab incision and the anvil inserted into the other stab incision. The stapler is discharged and the blade pushed to form the stoma that is approximately 10 cm in length.55 The stab incisions are oversewn, followed by a single inverting-suture pattern circumferentially around the entire staple line at a distance of 5 to 8 mm. The ileocecal fold, portions of the cecocolic fold, and the bowel serosa are apposed in a simple-continuous pattern to close the mesenteric defect and eliminate the potential for an internal hernia.51,55 A variation of this technique describes the resection of a 15- to 30-cm segment of the ileum or ileum and distal jejunum prior to performing the anastomosis. By constructing the distal free end of the small intestine adjacent to a jejunal mesenteric vascular arcade, some surgeons feel the chances of an inadequate blood supply to the anastomosis is decreased.54

Several studies have reported on prognosis and complications after cecal bypass.3,9,15,54 In one case series, five of six horses (83%) with cecal impaction treated by ileocolostomy returned to their previous activity with a minimal follow-up period of 6 months.51 Surviving until discharge were six of seven (86%) in another study.19 In a third study, nine horses that failed to respond to medical therapy received an ileocolostomy or jejunocolostomy.54 All horses survived until discharge, with all seven horses available for long-term follow-up (range, 7 to 54 months; mean, 1.5 years). Several important observations were made relative to complications in this study. Positioning the small intestine aborally on the RVC makes closure of the mesenteric defect technically difficult, predisposing the horse to entrapment or strangulation of the small intestine in the mesenteric defect. To avoid this problem, the small intestine should always be placed on the RVC facing orally and the mesentery closed. Another problem encountered was kinking at the anastomosis. Suturing a 5- to 10-cm segment of the distal small intestine to the colon proximal to the anastomosis is recommended to prevent this problem.54 A further recommendation was to evacuate the cecum prior to performing the anastomosis to avoid cecal impaction in the postoperative period. The authors emphasized the importance of gradual return to feed, because the most common postoperative complication was mild signs of colic within several days of reintroduction to feed. Although the cecum plays an important role in water absorption and bacterial degradation of dietary fiber,5,56 no detrimental consequences related to hydration and nutritional states have been observed with the bypass procedure.51,54

### Postoperative Care

Horses are treated with broad-spectrum perioperative antibiotics and NSAIDs. The antibiotics may be discontinued 24 hours after surgery or continued for a therapeutic treatment course of 5 to 7 days, depending on the amount of contamination that occurred during the surgical procedure. The NSAIDs are continued for 3 to 5 days. During the initial postoperative period, intravenous fluids should be provided at a slow but constant rate. After 12 to 24 hours, the horse should be offered small amounts of water. Once it has demonstrated a tolerance for oral fluid, the water intake is increased and the intravenous fluids decreased. Postoperative feeding is very important. It has been recommended that feed be withheld for a minimum of 36 to 48 hours, followed by grazing and feeding a bran mash with small quantities of good quality hay at frequent intervals.54

### Cecocolic or Cecocolic Intussusception

#### Pathogenesis

Cecocolic and cecocolic intussusception occur when the cecal apex invaginates into the cecal body (ceccocolic) or continues through the cecocolic orifice and enters the large colon (ceccocolic). Intussusception of the cecum was the most common cause of cecal obstruction in a report from the United Kingdom, whereas it accounted for only 3% to 3.5% of horses with primary cecal disease and for 1.3% of horses undergoing exploratory laparotomy for colic in other reports.9,8,57,59 The relative frequency of cecocolic compared with cecocolic intussusception varies markedly depending on the study.12,59 The etiology is unknown, but altered motility has been suggested to play a role. Dietary changes, cecal wall abscess, *Salmonella, Eimeria lanceolaturn*, *Strongylus vulgaris* arteritis, organophosphates, and administration of parasympathomimetic drugs have all been implicated as potential risk factors.4,8,59,62-64 Tapeworm...
infestation is often encountered in horses with cecal intussusception, leading some to speculate a causative association, possibly from mucosal inflammation initiating the intussusception. However, other studies have not found a difference in tapeworm infestation rates between horses with and without cecal intussusception. Young horses (less than 3 years) and Standardbreds appear to be at increased risk.

Clinical Signs and Diagnosis

Clinical signs may vary considerably depending on the degree of vascular compromise and mechanical obstruction of the ingesta. Approximately 55% of horses in one report presented with acute, moderate to severe pain requiring immediate surgical intervention, and 30% presented with a subacute form (3 to 8 days) characterized by intermittent mild to moderate pain with soft feces or diarrhea. A smaller group (13%) presented with a chronic form (6 to 180 days) characterized by weight loss, scant soft feces, and mild abdominal pain. Fever is common in horses suffering from this problem over a longer period of time. Cecocecal intussusceptions are more likely to be nonstrangulating, incomplete obstructions producing mild pain, and they develop into a chronic disease.

Cecocolic intussusceptions typically develop ischemic necrosis of the distal end of the intussusception, including the cecal apex and part of the body. Rectal examination may be unremarkable in horses with cecocecal intussusception, as the intussuscepted cecal apex may not be palpable and the colon and small intestine are usually not obstructed. In horses with cecocolic intussusception, the cecum may feel malpositioned or may not be palpable at all. A mass or edematous bowel may be palpable in the right caudal abdomen.

Ultrasonography may aid in the making the diagnosis. Frequently, the compromised portion of the cecum is sequestered within the colon (or cecum), rendering peritoneal fluid analysis an insensitive indicator of pathology. With time and progression of the disease, peritoneal fluid changes may be seen. Often, the diagnosis is made at surgery after the horse fails to respond to medical therapy.

Treatment

Surgical reduction with partial typhlectomy: The surgical approach is through a ventral midline celiotomy. During the abdominal exploration, the cecal apex is found to be intussuscepted into the body of the cecum in the case of a cecocecal intussusception, whereas the cecum is “absent” from its normal position (with a palpable mass in the right ventral colon) in the case of a cecocolic intussusception. In rare cases, the base of the cecum may be intussuscepted into the colon while the cecal apex remains everted. In these cases, the cecum cannot be exteriorized to the normal extent while the invagination is palpable at the cecal base. Manual reduction is attempted by inserting one hand to grasp and place traction on any portion of the cecum within the intussusceptum, while the other hand is placed on the colon over the intussuscepted cecum to gently massage the inverted cecum to an everted position. Approximately one third of cecal intussusceptions may be reduced in this manner. The intussusceptum is frequently vascularly compromised, necessitating a partial typhlectomy. To prepare for the partial typhlectomy, the lateral and medial cecal vessels are double-ligated with 0 absorbable suture. Doyen intestinal clamps are placed proximal to the intended amputation site across the cecum to decrease fecal contamination, and the surgical area is draped off. The compromised cecum is often too edematous to allow the use intestinal stapling instruments during the resection. After sharply resecting the compromised cecal apex and body, the cecum is closed using either an inverting or an appositional pattern, followed by an inverting suture pattern with no. 0 absorbable suture.

Cecal amputation through a colotomy: Manual reduction of cecocolic intussusceptions is frequently not successful because of edema and adhesion formation. In these cases, reduction of the intussusception should be approached through a colotomy. The large colon should be exteriorized from the abdomen and first evacuated through a pelvic flexure enterotomy if it contains an appreciable amount of ingesta. After closure of the pelvic flexure enterotomy, a second enterotomy is made on the ventral surface of the right ventral colon centered over or immediately distal to the intussusceptum. A sterile plastic bag or a plastic enterotomy drape with a 25-cm-long hole in the center can be sutured to the colon before the enterotomy is made to limit contamination during the colostomy (see Fig. 36-7, A). Attempts can be made to manually reduce the intussusception through the colotomy, but this is often unrewarding. In these cases, a partial resection of the invaginated cecum will facilitate reduction of the remaining cecum. The medial and lateral aspects of the inverted cecum are blindly ligated with two parallel transfixation sutures to occlude the cecal vessels. Overlapping mattress sutures, staples, or an encircling ligature with umbilical tape or a natural rubber ligature are placed to occlude the lumen of the cecum (see Fig. 36-7, C). The invaginated cecum is then transected and the remaining cecal stump reduced using both gentle traction on the cecal body and pushing the remaining inverted cecum out. The colotomy incision is closed with a two-layer inverting pattern using 2-0 or 0 absorbable suture. The now everted cecal stump is subsequently examined for viability. If necessary, further resection of the cecum is performed (see Fig. 36-7, D). The cecum is closed with a double-inverting pattern using no. 0 absorbable suture.

If the cecum cannot be reduced after partial resection within the colon, or if the remaining cecal stump is friable and necrotic, the cecal stump is left invaginated within the colon and a cecal bypass procedure is performed. In these cases, a partial typhlectomy is performed to remove as much of the necrotic cecum from inside the colon as possible, after which the cecal stump is sutured in a horizontal overlapping mattress pattern followed by a simple-continuous pattern. The colotomy incision is then closed and the surgical area lavaged. To prevent leakage of ingesta, the serosal surface of the cecum at its point of invagination into the colon is oversewn. However, complete oversewing at the point of intussusception may not be possible and may be unnecessary. The ileum is subsequently transected, and an ileocolostomy or jejuncocolostomy is performed adjacent to the closed colotomy incision (see “Jejuncocolostomy or
ileocolostomy” under “Cecal Impaction,” p. 442). The devitalized cecal stump is thought by some to slough inside the colon and pass in the feces, whereas others question whether this occurs.62,64

**Postoperative Care and Prognosis**

Horses are treated with intravenous fluids, broad-spectrum antibiotics, and NSAIDs. In cases of cecocolic intussusception with minimal contamination, the antibiotics may be discontinued 24 hours after surgery. Horses with cecocolic intussusceptions requiring cecal amputation within a colostomy are more likely to have been exposed to contamination and consequently require a therapeutic course of antimicrobial therapy. Postoperative abdominal lavage for 2 to 3 days also may aid in reducing the incidence and severity of postoperative peritonitis. The horse can be started back on feed 24 hours after surgery if there is no evidence of pain. The prognosis is related to the amount of cecum intussuscepted, the ability to manually reduce the intussusception without opening the colon, the amount of contamination at surgery, and the viability of the cecum or the remaining cecal stump.* The prognosis after surgical correction for cecocolic intussusception is good.60 Although a poor prognosis was associated with partial typhlectomy through a colotomy in one report,68 other studies revealed a good prognosis associated with this technique.62,69 Despite some contamination, which is inevitable during reduction through a colostomy, even with careful packing of the abdomen, clinical evidence of postoperative peritonitis is infrequent.62,69 In one report, four of six horses with irreducible cecocolic intussusception with ileal obstruction survived after a bypass procedure without partial typhlectomy of the invaginated cecum.57

---

*References 3, 24, 32, 58, 60, 62.
However, the complication rate associated with the bypass procedure compared with partial typhlectomy and reduction through a colotomy suggests that the bypass procedure should be reserved for those cases where reduction after partial typhlectomy is not possible.4,52,62,69

Cecal Perforation or Rupture
Cecal perforation has been described in several retrospective studies.19,34,39,72 Cecal perforation secondary to cecal impaction is well recognized.3,19,39 Primary cecal perforation, unrelated to cecal impaction, has been described to occur in horses during treatment for an unrelated disease. In these horses it appears to be associated with hospitalization, NSAIDs administration, or anesthesia. Primary cecal perforation has also been reported in periparturient mares.19,24,27,34,71 Dysstocia has been observed in approximately 50% of these horses. Horses with cecal perforation typically exhibit signs of pain soon after foaling, presumably as a result of cecal rupture from excessive pressure placed on the cecum during parturition. Primary cecal perforation has also been associated with tapeworm infestation.26 As discussed previously, some horses with cecal impaction caused by cecal dysfunction may rupture without demonstrating significant clinical signs.19,34 Consequently, it is not possible to know how many of these cases that have been described as primary cecal perforation have in fact been caused by a cecal dysfunction resulting in cecal distention caused by gas and fluids that went unnoticed prior to cecal perforation.

Cecal Volvulus or Torsion
Cecal volvulus or torsion secondary to large colon volvulus is not uncommon.3 Because of the substantial dorsal attachments of the cecal base to the body wall and colon, it is not common for the cecum to develop a primary torsion or volvulus. Incidental displacements of the cecum may be encountered at surgery and are sometimes classified as a torsion (usually 90 degrees). These typically are not a pathologic problem.35 Primary volvulus may be related to anatomic abnormalities such as hypoplasia of the cecocolic fold and the normal cecal attachments to the body wall.35,74 However, in one report, 9 of 96 horses (9%) with cecal disease were described to have primary cecal torsion with no apparent anatomic abnormalities.19 Horses with cecal torsion or volvulus are presented with a sudden onset of severe abdominal pain. Rectal palpation is typically not diagnostic. Peritoneal fluid protein and nucleated cell count may be elevated. The diagnosis is made during an exploratory laparotomy. Partial typhlectomy with resection of the compromised cecum is recommended. The prognosis will depend on the viability and amount of compromised cecal tissue remaining after partial typhlectomy. In one report, three of five horses (60%) with cecal torsion treated by partial typhlectomy survived until discharge.19 If extensive cecal damage extending to the cecal base is found at surgery, complete cecal amputation can be performed through a right flank approach with an 18th rib resection.47 Cecal amputation leaving part of the cecal cupula to form a conduit between the ileocecal and cecocolic junctions has also been described in a case with extensive cecal ischemia from prolapse through a flank wound.75 Recurrence has been reported after surgical correction in one horse with abnormal mesenteric attachments.15

Cecal Infarction
Cecal infarction has been reported to occur in 10 of 96 (11%) horses with cecal disease.19 Vermiform arteritis from Strongyloides vulgaris infestation and multifocal infarction from larval cyathostomes are two proposed etiologies.19,76 Mild abdominal pain increasing in severity over 24 hours is the most common clinical sign. Diarrhea, sudden severe pain, and acute cardiovascular collapse have also been described.1,19 Peritoneal fluid evaluation reveals changes consistent with intestinal ischemia.3,19 Rectal palpation may reveal a hard mass in the area where the cecum is located in approximately one third of the cases.19 Surgical intervention is based on persistent abdominal pain and peritoneal fluid abnormalities, with the diagnosis of cecal infarction made at surgery. Subtotal typhlectomy is the recommended treatment.19 In one report, seven of eight horses (88%) with cecal infarction treated by subtotal typhlectomy survived to discharge.19 Although complete typhlectomy requiring an 18th rib resection in left lateral recumbency has been described, the favorable prognosis with partial typhlectomy indicates that the more difficult procedure performed through a right flank approach is usually not necessary.19,47

Cecal Tumors
Primary cecal tumors have rarely been reported in horses.19,77,78 Three of 96 horses (3%) with cecal disease had primary tumors.19 All three horses were 20 years or older and were presented for chronic weight loss rather than abdominal pain. Histologic diagnoses were leiomyoma, hemangiosarcoma, and papillary adenoma. Treatment should be surgical resection if possible and feasible.

Miscellaneous
Other reported conditions include cecal abscesses that may be associated with adhesions.19,79 Horses may be presented with mild abdominal pain and peritoneal fluid changes consistent with peritonitis. Transrectal or transabdominal ultrasonography may aid in the diagnosis of cecal abscessation.19,79 The treatment consists of surgical resection of the abscess and adhesions. Cecocutaneous fistulas have also been described, occurring after repair of body wall hernias with hernia clamps.80 We have repaired several enterocutaneous fistulas that developed with entrapment of the cecal wall in an umbilical hernia with no history of hernial clamps. The prognosis after surgical repair is good.

LARGE COLON
Anatomy
The equine ascending colon begins at the cecocolic orifice and ends in the transverse colon. It measures approximately 3 to 3.7 m in length and has a capacity of 50 to 60 L. It is composed of the ventral and dorsal areas of the colon, which are connected by a short mesentery. Only rarely does
a mesenteric defect occur between the ventral and dorsal colons (Fig. 36-8). In situ, the large colon is further folded such that four segments are designated as the right and left ventral colon and the right and left dorsal colon. The transition from the left and right ventral colons forms the sternal flexure, and the transition from the left and right dorsal colons forms the diaphragmatic flexure. The maximal diameter is seen in the right dorsal colon and can reach 50 cm. The narrowest diameter occurs in the left dorsal colon, which measures about 8 to 9 cm. The bands of the colon (teniae coli) support the colon. The ventral colon has four bands, of which the two ventral ones are free, and the two dorsal ones are associated with the mesentery. The medial dorsal band is associated with the colonic vasculature. The pelvic flexure has one band, which can be palpated on rectal examination. The left dorsal colon has one band, which is joined by two other bands in the right dorsal colon. The roles of the teniae coli are to provide mechanical support to the colon, to maintain orientation of the colon within the abdomen, and to allow distention and contraction of the intestinal segments depending on the degree of ongoing fermentation. The teniae are composed of smooth muscle and collagen in varying proportions, depending on the role of each intestinal segment. In the ventral colon, the site of bacterial fermentation, the teniae have a greater proportion of elastin than in the dorsal colon. In the right dorsal colon, the site of transport and regulation of ingesta through the transverse colon, smooth muscle cells are present in greater proportion.81

The blood supply to the ascending colon is derived from the cranial mesenteric artery. The colic branch of the ileoceccolic artery supplies the ventral colon to the pelvic flexure, where it joins the right colic artery, another branch of the cranial mesenteric artery. The middle colic artery, also a branch of the cranial mesenteric artery, provides blood supply to the transverse colon and to the initial part of the small colon. The microvascular circulation of the ascending colon has been well described.82 The arteries branch from the colonic vessels every 2 cm and anastomose with vessels lying orally and aborally to form a colonic rete before continuing into the colonic tissue. The function of the colonic rete is unclear, but it may provide collateral blood supply, increasing the resistance of the colon to thromboembolic disease.83 Vessels enter the submucosa through the tunica muscularis to form a complex anastomosing network of submucosal vessels. The extensive collateral supply to the colonic tissue can be expected to enhance healing, particularly where there are areas of devitalized tissue. Arterioles ascend from the submucosal plexus to the mucosa, where an extensive capillary network forms around the colonic glands (Fig. 36-9). This capillary network is drained by more sparsely distributed venules (Fig. 36-10). The submucosal venous plexus is characterized by regular mural helical smooth muscle constrictions that give the veins a sacculated appearance. The venous network is proposed to act as a capacitance system, storing large volumes of blood, which can be actively or passively directed into the systemic circulation as required. Alternatively, because of the large volumes of blood stored within the ascending colon, these smooth muscle constrictions may aid in maintaining blood flow through a low pressure system.82 The abundant colonic blood supply makes it more susceptible to severe intraluminal hemorrhage after enterotomies.83

**Physiology**

The most critical functions of the equine large colon are storage, microbial digestion, and fluid absorption. In a 24-hour period, the large intestine must recover a quantity of water approximately equivalent to the extracellular fluid volume of the horse (approximately 20% to 30% of body weight, or 90 to 135 L for a 454-kg horse).6 The storage function of the large colon allows time for microbial digestion and absorption of volatile fatty acids, the main source

![Figure 36-9. Scanning electron micrograph of a vascular replica at the luminal surface of the ascending colon. The capillary network ascends around the colonic glands (G) to the lumen where the capillaries (C) in a network surrounding adjacent glands anastomose and look like a honeycomb.](image)
of energy in the horse. The principal mechanism for delay in transit is the retropropulsive activity initiated in a pacemaker region near the pelvic flexure (approximately 30 cm aboral to the termination of the medial and lateral free teniae of the left ventral colon). The coordinated contractions originating at the pelvic flexure pacemaker promote physical separation of small, well-digested particles, which are propelled aborally, and of coarser particles, which are propelled orally for further digestion. This may explain the roles of poor-quality feed and dentition in the development of large colon impaction.

Large Colon Tympany
Large colon tympany (gas colic, spasmodic colic) is the most commonly reported colic in horses. It is thought to result from excessive gas fermentation in the colon, resulting in distention and pain. In one study evaluating risk factors for simple colonic obstruction and distention colic in horses (including large colon impaction), an increased risk was associated with crib-biting or windsucking, increasing number of hours spent in a stable, recent change in the regular exercise program, lack of administration of ivermectin or moxidectin anthelmintic in the previous 12 months, and a history of travel in the previous 24 hours. Other factors that increased the risk of simple colonic obstruction and distention included history of previous colic, recent (less than 4 weeks) lameness, and increased time since last dental care. An association between tapeworm infestation and spasmodic colic has been demonstrated. Horses fed a hay and grain diet containing large amounts of soluble carbohydrates and less fiber had decreased water content in ingesta and increased gas, which predispose to gas colic. Although large colon tympany can be self-limiting, it is thought to precede large colon displacements; therefore, identification of risk factors in affected horses may help decrease the risk of future occurrences.

Diagnosis
Horses examined for large colon tympany have acute pain and may show signs of visible external abdominal distention. Although in pain, they are minimally compromised and clinicopathologic parameters including abdominocentesis remain within normal reference range. The challenge for the clinician is to differentiate this type of colic from other, more serious causes of abdominal pain. The differential diagnosis for gas colic resulting in large colon distention includes large colon displacement, large colon torsion, ileus (impending colitis), and aboral obstruction (transverse or small colon obstruction). Rectal palpation reveals moderate to severe gas distention of the large colon.

Treatment
Treatment includes administration of analgesics and withholding feed. The response to medication is favorable and, if the diagnosis is correct, the horse will remain comfortable. Lack of response to analgesics may indicate a more serious problem. If the response to treatment is unsatisfactory, early referral is recommended, considering that large colon volvulus is a differential for this condition.

Large Colon Impaction
Large colon impaction is the second most commonly reported cause of colic in horses, and it is the most frequent type of simple obstruction. It represents up to 13.4% of colics examined at referral centers. Risk factors identified in one study included crib-biting or windsucking, increasing number of hours spent in a stable, recent change in the regular exercise program, absence of administration of ivermectin or moxidectin anthelmintic in the previous 12 months, and a history of travel in the previous 24 hours. Additional factors identified in that study included history of previous colic, recent (less than 4 weeks) lameness, and
increasing time since last dental care. In another study, 79 of 147 horses (53.7%) had a change in routine in the 2 weeks prior to development of a large colon impaction, and 17 of 147 (11.5%) developed the impaction while hospitalized for a reason other than gastrointestinal disease. Decreased water intake and parasites are factors also mentioned although not well documented. High grain diets may predispose to colonic impactions, since grain feeding was shown to be associated with an internal fluid flux and subsequent dehydration of ingesta, setting the stage for impaction. Right colon dry-matter content was higher when grain was part of a free choice hay diet. In another study, water consumption was 40% greater in ponies offered drinking water under cold weather conditions, suggesting that cold weather may predispose to colonic impaction. Hospitalization and general anesthesia have been suggested as risk factors for the development of impaction colic. In one study, 37 of 85 hospitalized horses (43.6%) developed postoperative reduced fecal output, and 10 horses (12%) developed signs of colic; two of nine horses that had a rectal examination had pelvic flexure impactions. In that study, administration of phenylbutazone decreased the risk of dehydration of ingesta, setting the stage for impaction. Amitraz, an acaricide, has been used to induce experimental large colon impaction in horses. Topical spraying of horses with amitraz was associated with systemic illness and impaction colic in three horses. Amitraz, atropine, glycopyrrolate, and morphine significantly prolonged intestinal transit time in horses. Atropine (0.044 mg/kg and 0.176 mg/kg IV) resulted in decreased intestinal motility and decreased appetite for 2 to 7½ hours after injection; signs of abdominal pain were observed in 3 of 10 ponies after administration. Topical ocular administration of 1 mg of atropine hourly resulted in decreased intestinal motility (as assessed by auscultation for 2 to 18 hours after administration), and signs of abdominal pain were observed in four of six horses. Subconjunctival administration of 3 mg of atropine resulted in decreased intestinal sounds in three of six horses, and signs of abdominal pain in one. Lowering the luminal temperature to 20° C (room temperature) over a 100-cm length of colon cranial and caudal to the pelvic flexure for 2 hours significantly decreased conduction velocity, as well as amplitude and duration of pressure peaks in the intestinal wall. These findings have direct relevance to surgery of the large colon, where the colon is exteriorized from the abdomen, sometimes for prolonged periods of time, and where luminal lavage is performed. Minimizing the time of exteriorization and using warm water for luminal lavage may help the colon recover from the effects of reduced temperature.

The role of intestinal parasites on pelvic flexure motility has been evaluated. In one study, arteritis of the cranial mesenteric artery induced by inoculation of Strongylus vulgaris larvae resulted in reduced relative colonic blood flow; but it did not cause altered motility patterns. In another study, increased motility patterns were observed in the cecum and colon at intermittent intervals for several days after infection. Horses with chronic (more than 24 hours) obstructions of the large colon or with previous obstruction had decreased neuron density in the pelvic flexure, which may predispose to future obstructions. Megacolon with myenteric hypoganglionosis has been described in a 6-month-old foal with severe large colon impaction and colic. Recurrent impactions of the large colon were diagnosed in a mare with eosinophilic enterocolitis. In that mare, diarrhea, hypoproteinemia, and weight loss characteristic of the disease were not present, and the intestine appeared grossly normal at surgery and at postmortem examination. These cases support the use of intraoperative intestinal biopsies in horses with unexplained recurrent large colon impaction.

Large colon impactions usually affect horses older than 1 year, although miniature horses may be predisposed to impactions as foals. Historically, horses are presented to referral centers for chronic colic (i.e., of longer than 24 hours' duration).

Diagnosis
The most common location for large colon impaction is the pelvic flexure, followed by the right dorsal and transverse colon. On physical examination, horses typically show mild to moderate abdominal pain, decreased or absent intestinal sounds, decreased or absent fecal production, and occasionally mild to moderate abdominal distention. Nasogastric reflux is rarely present. Rectal palpation is diagnostic in cases of pelvic flexure impaction. However, impactions of the right dorsal and transverse colon can be difficult to palpate in adult horses. When a large colon impaction is suspected on the basis of rectal palpation, it is essential to differentiate that from a large colon displacement with secondary right dorsal colon impaction. Prolonged treatment of a large colon displacement with fluids and cathartics could result in preoperative or intraoperative colonic rupture.

In the case of a large colon displacement, the right dorsal colon may become severely impacted; during rectal palpation, when the hand follows the colon, it travels to the right, and lateral to the cecum. This is in contrast to a pelvic flexure impaction where the end of the pelvic flexure can readily be identified. Another important differential diagnosis of large colon impaction is small intestinal obstruction, which can result in dehydrated dry fecal contents in the large colon as identified by palpation. In contrast to large colon impaction, the teniae and haustra of the ventral colon in such cases become more prominent and distinguishable.

Laboratory data typically observed in horses with large colon impaction show mild to moderate dehydration, a normal leukogram, and normal electrolyte data and blood gas analysis. The abdominocentesis results should be within normal range. Deteriorating cardiovascular status or peritoneal fluid changes are an indication of bowel degeneration.

Treatment
Medical treatment of large colon impaction includes fluid therapy, analgesics, cathartics, and withholding of feed until the impaction is resolved. Intravenous fluids are reserved for impactions of longstanding (more than 24 hours) duration, when dehydration is documented, or when nasogastric reflux is present precluding the use of enteral fluid therapy.
Balanced electrolyte solutions are administered at twice the maintenance rate or 120 mL/kg per day, both to restore circulating blood volume and to allow secretion of fluid into the large colon in response to cathartics. Overhydration in combination with an oral cathartic such as magnesium sulfate is thought to promote rehydration of ingesta. Systemic rehydration should be performed before administration of cathartics.

Enteral fluid therapy can complement and even supplement intravenous fluids. Advantages of enteral fluid therapy include administration of fluid directly in the gastrointestinal tract, stimulation of colonic motility through the gastrocolic reflex, decreased expense, and decreased need for precise adjustment of fluid composition. Enteral fluids can be administered by intermittent nasogastric intubation, or by nasal placement of an indwelling feeding tube (18 French equine enteral feeding tube, Mila International, Florence, Ky), allowing continuous fluid administration. An isotonic electrolyte solution can be made by mixing 5.27 g of NaCl, 0.37 g of KCl, and 3.78 g of NaHCO₃ per liter of tap water. This solution results in electrolyte concentration of 135 mEq/L of Na, 95 mEq/L of Cl, 5 mEq/L of K, and 45 mEq/L of HCO₃⁻, with a measured osmolality of approximately 255 mOsm/L, representing a slightly hypotonic electrolyte solution compared with plasma. Plasma electrolyte concentrations remained within normal range with this solution compared with the marked hypernatremia and hyperchloremia observed when 0.9% saline is administered enterally. Despite the fact that normal horses can tolerate up to 10 L hourly through intermittent nasogastric intubation, it is usually not possible to administer more than 5 L every 2 hours in horses with impactions, because these horses start to reflux when more fluid is administered. Therefore, intermittent intubation is used, allowing administration of approximately 60 L of fluids per day. When continuous enteral fluids are given, a greater rate of administration is tolerated, and horses can be given between 4 and 10 L/hour. At the higher rate of 10 L/hour, mild signs of abdominal pain were observed in normal horses, and in horses with large colon impaction, a rate of 5 L/hour is better tolerated. For enteral fluid therapy, the fluid used can be water, or water and electrolytes. In one study, right dorsal colon ingesta hydration was significantly increased after enteral fluid therapy combined with enteral administration of magnesium sulfate.

Cathartics are useful to increase the amount of water in the large colon or to promote ingesta transit. Mineral oil is a mixture of aliphatic hydrocarbons obtained from petroleum; it is indigestible and absorbed to a limited extent. It is an intestinal lubricant that can also serve as a marker of intestinal transit. Administration of 5 to 10 mL/kg is usually recommended, and oil should be evident in the feces 12 to 24 hours after administration. Unformed feces were apparent 18 to 24 hours after its administration in normal horses. Administration to normal horses decreased glucose absorption and intestinal transit time. Chronic usage can result in a foreign body reaction in the intestinal mucosa. Careful administration is necessary, since inadvertent administration into the lungs results in lipid pneumonitis, which is severe and often fatal. Mineral oil is easily confused with propylene glycol, used in the treatment of ketosis in cattle; inadvertent administration of propylene glycol was the cause of death in a horse.

Dioctyl sodium sulfosuccinate is an anionic surface-active agent that by lowering surface tension may facilitate penetration of the fecal mass by water and fats. Effects on motility and secretion are also attributed to this product. The recommended dose range is 16.5 mg/kg to 66 mg/kg, and the maximal recommended dose is 0.2 g/kg. Death because of circulatory shock can occur at doses of 1 g/kg. In one study in normal horses, toxic signs were observed at a dosage of 50 mg/kg. It is important to correctly label the product to avoid overdosing. Its advantage is that it requires a low volume of administration. However, the drug's low margin of safety and lack of efficacy at low dosages make its use questionable. Concurrent absorption with mineral oil may result in emulsification and subsequent systemic absorption of oil. Therefore, the use of the combination is frequently discouraged, although the significance of this finding is unknown.

Osmotic or saline cathartics such as magnesium sulfate or sodium sulfate are the most effective products to increase colonic water content. Because of their efficacy, these products should be used after systemic rehydration. Recommended dosages are 0.5 to 1 g/kg. Absorption of magnesium resulting in signs of toxicity was reported in two horses that had received a combination of dioctyl sodium sulfosuccinate and magnesium sulfate. Raw linseed oil produced from flaxseed was a commonly used laxative for the treatment of impactions. The addition of metallic salts and bile oil or oil纯e enhances its properties as a wood preservative and is highly toxic. Only raw linseed oil should be used. Administration of 2.5 mL/kg to normal horses resulted in watery diarrhea, anorexia, mild signs of colic, and neutropenia. Although raw linseed oil has greater laxative effects than mineral oil, the toxic effects may preclude its use, particularly in horses with compromised intestinal mucosa. Polyethylene glycol 3350 is an effective osmotic laxative that is used in humans for the treatment of constipation or for colonic cleansing. This product has not been evaluated rigorously in horses, although we have used it successfully to treat large colon impactions. Its cost is much greater than that of the other cathartics mentioned. Castor oil has been used as a model for experimental colitis in ponies. Its use for the treatment of impaction colic is not recommended.

Analgesics are indicated as part of the management of large colon impaction. NSAIDs are commonly used. Use of low-dose flunixin meglumine may help control pain without affecting large colon motility. In the course of treatment of severe impactions, some horses may require intermittent dosing with xylazine to relieve intestinal spasm. Alternatively, a constant-rate infusion of lidocaine can be used to modulate pain.

Prognosis

Most horses respond well to medical therapy. In one study, only 24 of 147 horses required surgery. Indications for surgery included uncontrollable pain, deteriorating cardiovascular status, or peritoneal fluid changes indicating bowel compromise. Of the horses that went to surgery, five were euthanized after tearing of the colon during exteriorization.
Surgical management of large colon impaction involves evacuation of the colon by pelvic flexure enterotomy. Complications of surgery include intraoperative rupture of the colon, postoperative diarrhea, incisional drainage, and, rarely, septic peritonitis. The prognosis for large colon impaction is excellent, and the majority of horses respond to medical therapy. The prognosis is better for horses treated medically than surgically. In one study, long-term outcome for horses treated medically was 95.1%, compared with 57.8% for horses treated surgically. The most common complication was jugular vein thrombophlebitis, so catheter sites should be monitored carefully. In the management of these horses, it is important to avoid risk factors that predispose to impactions. These horses are at risk for re-impaction if the same conditions remain. A small number of horses require permanent dietary modifications to avoid reimpaction.

Sand Impaction

Accumulation of sand in the equine large colon can result in variable signs, including colic, diarrhea, weight loss, and poor performance. Sand should be considered in the evaluation of chronic diarrhea in foals and adult horses. Risk factors for sand impaction include insufficient roughage in the diet, access to sand, and mineral composition of the soil. Sand impaction has been diagnosed in horses that were exposed to sand 3 to 8 weeks before examination. Higher incidences of sand colic are reported in California, Florida, Michigan, and coastal regions. Although most horses with sand impaction are older than 1 year, sand accumulation has been documented in foals. Miniature horses may also be predisposed to sand impaction because of environmental and management practices.

Diagnosis

Horses with sand impaction manifest signs similar to those of large colon impaction, unless a concurrent large colon displacement or torsion is present. Large colon displacements or torsion were identified in 10 of 40 (25%) and 26 of 48 (54%) of horses with sand impaction. These clinical signs include mild to moderate abdominal pain, reduced fecal production, and decreased intestinal sounds. The sound of sand may be auscultated when the ventral abdomen is auscultated behind the xyphoid. These horses are responsive to analgesics, and signs can be present for several weeks. The cardiovascular status should be normal unless dehydration or intestinal devitalization has occurred. Occasionally, horses with sand impaction show signs of endotoxemia, presumably as a result of mucosal or intestinal damage associated with the weight and abrasiveness of the sand. Ultrasonic evidence of large colon impaction is rarely palpated on rectal examination; however, in most cases only after receiving several doses of sand, and after several repeated 5-minute auscultation periods. Rectal palpation of horses with sand impaction most commonly reveals distention of the cecum or large colon. The impaction is rarely palpated on rectal examination; however, if coarse sand is present, it may be palpated through the intestinal mucosa.

Abdominal radiography provides the best method to evaluate the amount of sand accumulation, and it serves as a tool for monitoring disappearance of sand with treatment (Fig. 36-11). Imaging of the cranioventral abdomen is the most useful projection. Abdominal ultrasonography can be used to diagnose sand impaction, but it is best used in combination with abdominal radiography to monitor clearance of the sand. Ultrasoundographic evidence of a horse showing accumulation of sand in the ventral colon (arrows).
of sand accumulation is more subjective and includes close and increased contact of the large colon with the ventral body wall, decreased or absent intestinal motility, and hyperechoic acoustic shadowing. In one study, radiography and ultrasonography outcomes were similar in only 50% of cases. Because ultrasonography is more readily performed and can be easily repeated, it is thought to be a useful tool for monitoring once a diagnosis has been made, although repeated radiographs may be indicated when results of the ultrasonography are equivocal.

**Treatment**

Medical treatment of sand impaction includes removing the horse from access to sand, rehydration by intravenous or oral methods, and the use of laxatives. Mineral oil is usually not effective, as it will pass around the sand. Magnesium sulfate or psyllium is used to promote evacuation of sand. In one study, psyllium failed to increase evacuation of sand in an experimentally induced model of sand impaction. However, numbers were small and the model may not reflect naturally occurring disease. In a clinical study, horses with sand impaction that were refractory to treatment were responsive to administration of magnesium sulfate and mineral oil.

Monitoring of the resolution of the impaction can be performed using abdominal radiography or ultrasonography. Horses with sand impaction can develop abnormal motility patterns and subsequent large colon displacement. These horses have more pain and develop gas distention of the large colon. Surgical intervention is indicated when a displacement is suspected or diagnosed, when abdominal pain is uncontrolled, in the presence of deteriorating cardiovascular parameters, or when there is evidence of intestinal devitalization. Standing flank laparotomy does not allow sufficient access to the large colon for evacuation in the presence of sand, and injection of the impaction is not successful in providing relief.

Therefore, a surgical approach through a ventral midline is recommended. At surgery, the colon is evacuated through a pelvic flexure enterotomy (Fig. 36-12). The most common location for accumulation of sand is the right dorsal colon, but any location, from the ileocecal junction to the small colon, is possible, and multiple impaction sites are commonly encountered. Care must be exercised during exteriorization of the large colon, since the weight of the sand predisposes the colon to rupture, especially in chronic cases. To facilitate exteriorization, the horse may be tilted toward the left side of the abdomen. In addition, the minimal length of large colon necessary to safely perform a colotomy should be exteriorized; as the colon is evacuated, more of its length can be carefully exteriorized from the abdomen.

**Prognosis**

Results of surgical treatment of sand impaction report a good long-term survival. The most common complication is postoperative diarrhea, but this complication is commonly noted after surgical evacuation of the large colon for any reason. Other complications include peritonitis associated with intestinal devitalization from pressure necrosis.

Prevention of sand impaction includes provision of adequate roughage, feeding off the ground, and provision of additional roughage when pastures are insufficient. The use of different formulations of psyllium (pellets or flakes) has been advocated at different dosage regimens (once a day for 3 weeks, then 1 week off, to twice a day for 2 weeks, then 1 week off), but the efficacy of these different dosage regimens in prevention of further sand accumulation has not been documented. There is concern that long-term use of psyllium results in alteration of the colonic microflora with subsequent bacterial digestion of the psyllium and decreased efficacy; this is the rationale behind interrupted administration.

**Enterolithiasis**

Obstruction of the large or small colon by enteroliths is a well-documented cause of intestinal obstruction in the horse. Risk factors include geographic location (with California and Florida having high prevalence for this cause of colic), breed predisposition (e.g., Arabians and Arabian crosses, Morgans, American Saddlebreds, donkeys, and Miniature Horses), feeding alfalfa hay, and less than 50% of time spent outdoors. Other factors to explain why other horses fed the same diet in the same geographic area do not develop enteroliths are as yet unidentified.

**Diagnosis**

Enterolithiasis can result in acute severe luminal obstruction or cause intermittent mild signs of colic, depending on the location and size of the enterolith. Those in the large colon are usually localized in the right dorsal colon and cause mild signs of intestinal discomfort. Once they migrate into the transverse or small colon, signs of acute luminal obstruction develop, with progressive abdominal distention. Although this condition causes a simple colonic obstruction, transmural pressure necrosis can occur. Critical attention to results of the abdominocentesis helps determine
such occurrence. An increase in total protein above the normal range and an increase in white blood cell count can alert the clinician to such occurrence.

Physical examination parameters also vary, depending on the location of the enterolith and whether intestinal devitalization has occurred. Rectal palpation may be normal or may reveal large colon distention. The enterolith can rarely be palpated. Results of the abdominocenteses are often normal, although an increased total protein is an early sign of intestinal devitalization. Radiographs are a useful diagnostic method for the detection of enteroliths, although the sensitivity and specificity vary depending on the location of the enterolith and the prevalence of the disease for the hospital population. In one study performed in a high-prevalence area for enteroliths, the sensitivity of radiographic diagnosis of enterolithiasis was 84.3% for those located in the large colon, compared with 50.0% for those located in the small colon. The mean overall positive predictive value for radiographs was 96.4%, and the negative predictive value was 67.5%.141

Surgical removal is indicated. If the enterolith is located in the large colon, the large colon is evacuated via a pelvic flexure enterotomy. A second enterotomy may be required in the right dorsal colon if the enterolith is too large to be evacuated through the pelvic flexure enterotomy. If the enterolith is lodged in the transverse colon, retrograde flushing by enema can facilitate its movement back into the dorsal colon. If the enterolith is in the small colon, it is removed by a small colon enterotomy. A partial-thickness enterotomy can facilitate movement of the enterolith to a more accessible portion of the small colon. If there is significant pressure necrosis of the intestinal wall at the site of the obstruction, a resection may be required.

Prognosis
The prognosis is usually excellent. However, local necrosis of the intestine in an area that cannot be exteriorized, such as the transverse colon, is associated with a grave prognosis. In one study, bypass of the transverse colon by end-to-side anastomosis of the ventral colon to the small colon was successful in a Miniature Horse with intestinal necrosis after obstruction by a fecalith in the transverse colon. The recurrence rate of enteroliths is unknown, but dietary modifications such as avoidance of alfalfa hay are usually recommended. Other recommendations include removing horses from dirt or gravel, which can serve as a nidus, adding psyllium to the diet, and adding cider vinegar (1 cup twice daily) to the diet. In geographic areas where the water has a high mineral concentration, providing an alternate source of water can be useful.140 Wheat bran should be minimized because of its high phosphorus content. Control of the dietary cation–anion balance (DCAB) has been suggested, although the benefits are unproven.143 The target DCAB, calculated by the following equation:

$$DCAB = ([Na] + [K] + 0.15 [Ca] + 0.15 [Mg]) - ([Cl] + 0.25 [S] + 0.5 [P])$$

is +200 to 300 mEq/kg. Grass hays and cereal grains have a DCAB within that range, whereas that of alfalfa is higher.

Large Colon Displacement
The equine large colon, because of its lack of mesenteric attachment to the body wall, is freely mobile and prone to displacement. In addition, normal longitudinal shortening of the left colon, promoted by contractions of the longitudinal layers, move the pelvic flexure toward the diaphragm, followed by backward movement toward the pelvis during relaxation; alterations in this motility pattern, initiated at the pelvic flexure pacemaker, could result in displacements and torsion.87 The normal equine diet is composed of soluble and insoluble carbohydrates. Insoluble carbohydrates are digested by microbial fermentation, resulting in production of volatile fatty acids that are absorbed for energy production. When excess soluble carbohydrates are fed, alterations in the microbial population of the large colon may result in excessive fermentation, gas distention, and subsequent displacements.

Large colon displacements have been classified into left dorsal displacement of the large colon (also referred to as nephrosplenic entrapment or renosplenic entrapment), right dorsal displacement of the large colon, and nonstrangulating volvulus of the large colon. The large colon may adopt a location intermediate to these displacements, such that the exact description of the displacement can be difficult to describe.

Nephrosplenic Entrapment
Nephrosplenic entrapment (also termed renosplenic entrapment or left dorsal displacement of the large colon) is a form of nonstrangulating large colon displacement in the horse, in which the left dorsal and ventral colons migrate lateral to the spleen in a dorsal direction until entrapped in the nephrosplenic space (Fig. 36-13). It has been reported in horses of any age, and in foals as young as 9 months.144 Although one report mentions the increased prevalence in male horses, others have not substantiated that finding.144-146 Miniature horses and pony breeds have not been reported to acquire this problem. It is theorized that excessive gas formation within the left colon, perhaps in association with abnormal motility, causes the left colon to displace lateral to the spleen and dorsally into the nephrosplenic space; alternatively, horses may displace during rolling episodes.86,144-149 In most cases, there is also ventromedial rotation of the left colon, such that the left dorsal colon is rotated ventral to the left ventral colon. The weight of the colon causes the spleen to displace medially and ventrally, and to become congested. Because of impaired flow of ingesta over time, with duration there is also concurrent impaction of the left dorsal colon. With continued gas formation, the sternal and diaphragmatic flexures can migrate cranial and dorsal to the stomach and become lodged between the stomach and the left lobe of the liver.150 A displacement classified as type II in one report.150 Nephrosplenic entrapment is a nonstrangulating lesion of the large colon; however, when duration of the condition increases to longer than 24 hours, colonic congestion and edema can develop, and mural damage may follow.147 Obstruction to gastric outflow occurs because of pressure of the colon on the duodenum, or tension on the mesentery. Entrapment of the small colon or small intestine in the
nephrosplenic space have been described, but these conditions are rare.152,153

Horses with nephrosplenic entrapment show variable degrees of pain depending on the location of the colon, the amount of gas distention, and the presence of secondary gastric distention. Location of the colon lateral to the spleen is associated with minimal to no discomfort and is found in the resolving stages of the displacement. Entrapment of the colon within the nephrosplenic space with the spleen in a relatively normal position is a very painful condition. Affected horses crouch, want to go down, and often lean to the left. When the spleen is pushed away from the body wall and displaced ventrally by the colon, effectively opening the nephrosplenic space, there is less pressure on the colon, and horses show only mild signs of abdominal pain.

**DIAGNOSIS**

The diagnosis of nephrosplenic entrapment is based on the presence of abdominal pain (which can be mild to severe, depending on the location of the colon and the degree of gas distention) and relatively normal cardiovascular parameters, consistent with a simple obstruction. The complete blood count and blood chemistry values should be normal or consistent with mild dehydration. A low packed cell volume (PCV) in the face of dehydration has been reported as an indication of red blood cell sequestration in the spleen. The abdominocentesis results should be within normal range, and collection of splenic blood (characterized by a higher PCV than in peripheral blood) is supportive of a diagnosis of nephrosplenic entrapment. In one study, these results were obtained in 25% of horses at admission.145 Horses with an increased white blood cell count (WBC) in the peritoneal fluid were more likely to suffer from a longer duration of the condition and to be treated surgically.146 Nasogastric reflux is commonly obtained in horses with nephrosplenic entrapment as a result of pressure on the duodenum or mesenteric tension. Up to 43% of horses with nephrosplenic entrapment were reported to have nasogastric reflux.144 In one study, resistance to nasogastric intubation was encountered in horses with displacement of the sternal and diaphragmatic flexures dorsal to the stomach.

An ultrasonographic examination of the abdomen may serve as an adjunctive tool in the diagnosis of nephrosplenic entrapment, and it was diagnostic in 88% (36 of 41) horses with nephrosplenic entrapment.154 A 2.5- or 3.5-MHz ultrasound probe is placed over the 15th to 17th intercostal space in a direction parallel to the ground, and the spleen is imaged. In the normal horse, the left kidney is imaged deep to the spleen. In horses with nephrosplenic entrapment, the presence of gas-filled colon dorsal to the spleen precludes imaging the kidney. Finding ventral displacement of the dorsal aspect of the spleen is also consistent with nephrosplenic entrapment. If the colons are displaced lateral to the spleen, then imaging of the spleen is obscured as well. It is important to direct the probe in a horizontal direction; if the probe is angled in a dorsoventral direction, the kidney can occasionally still be imaged, giving a false-negative diagnosis. The inability to image the left kidney is supportive only of a nephrosplenic entrapment and should be used in conjunction with rectal palpation. Nonspecific large colon distention or the normal presence of small colon in the nephrosplenic space can impair imaging of the left kidney.155 In addition, if the colon is filled with fluid, imaging of the left kidney is still possible, but the entrapped bowel is also seen.154

Rectal palpation remains the mainstay of diagnosis of nephrosplenic entrapment. On palpation, the left colon is most often gas distended, and the ventral colon is located dorsal to the left dorsal colon; often, an impaction of the left dorsal colon is present as well. The colon can be followed up into the nephrosplenic space. It is important for the correct diagnosis to follow the colon into the nephrosplenic space, because in other conditions (ranging from gas colic to large colon torsion), the colon may assume a dorsal position within the abdomen, leading to a false diagnosis of nephrosplenic entrapment.156 This could be disastrous if nonsurgical management is attempted and the horse effectively has
a large colon torsion. Rectal palpation correctly identified left dorsal displacement of the large colon in 61.2%, 68.7%, and 72% of cases in three studies, although an early study reported a much lower rate of correct identification (only 18%). Rectal palpation can be impaired by patient size, temperament, or the presence of severe distention.

A thorough physical examination, rectal palpation, and abdominal ultrasonography should be performed in horses diagnosed with nephrosplenic entrapment, because a small number of them will have another primary lesion involving another segment of the gastrointestinal tract. Gastric rupture, small intestinal volvulus, ileal impaction, large colon displacement, large colon volvulus, cecal torsion, and small colon obstruction have been documented in association with nephrosplenic entrapment.

**TREATMENT**

Once a diagnosis of nephrosplenic entrapment has been made and the clinician is confident that there are no other abnormalities present, options for treatment are evaluated. These include medical therapy with intravenous fluids and withholding of feed; exercise with or without the use of a pressor agent; rolling under general anesthesia, with or without the use of pressor agents; standing flank laparotomy; and ventral midline celiotomy.

**Medical treatment**

Medical therapy with intravenous fluids supplemented with calcium gluconate is indicated when the colons are located lateral to the spleen. This type of treatment was successful in nine affected horses. When the colons are localized in the nephrosplenic space and the horse is in pain, nonsurgical management can be attempted. In one study, horses that were successfully treated nonsurgically had a shorter duration of clinical signs, a lower peritoneal fluid WBC, and a higher blood lymphocyte count than horses treated surgically. In that study, failure at nonsurgical correction was also felt to be related to severity of gas distention, which would also increase with duration. It is important to emphasize again that the diagnosis must be certain before attempting this option.

With all nonsurgical options, phentylephrine is often used to cause splenic contraction and facilitate correction. Bleeding the horse was described in the early literature to reduce splenic size, but this seems unnecessary and possibly detrimental. Phentylephrine (Neo-Synephrine HCl, 10 mg/mL, Winthrop Pharmaceuticals, New York, NY) is an α₁-adrenergic receptor agonist that causes vasoconstriction in most vascular beds, and splenic contraction. In one study, the splenic area was reduced to 28% of baseline and thickness to 48% of baseline after administration of phentylephrine at 3 µg/kg/min over 15 minutes. Side effects were minimal at that dose and included hypertension and reflex bradycardia. We use a total dose of 10 mg for horses with a body weight of 450 kg or less and 20 mg for larger horses, diluted in 50 mL of saline and given slowly intravenously over 5 minutes.

Vigorous exercise is an option for correction of this problem, providing the horse is not lame. This is more successful when performed early in the course of the disease, before large colon distention develops. If there is significant distention of the left colons, they can be trocarized before exercise. For trocarization, an area over the left flank is clipped and prepared for aseptic surgery. A 14-gauge angiocatheter with a catheter extension is used to puncture the flank in a perpendicular direction. The end of the catheter extension is placed in a water container to facilitate observation of gas exiting the colons. Once in place, the trocar portion of the catheter is withdrawn for a few millimeters to avoid laceration of the bowel. The catheter may need to be inserted farther as the colon is deflated. When doing so, care must be taken not to lacerate the tip of the catheter with the trocar. Rectal palpation can help manipulate the colon to facilitate gas evacuation. Once done, the trocar portion of the catheter is removed and 1 to 2 mL of gentamicin is injected as the catheter is withdrawn. Once the trocarization is completed, phentylephrine is administered and the horse is exercised either on a lunge line or in a small paddock for approximately 15 to 30 minutes. Rectal palpation is performed to ascertain the position of the colon. Exercise can be repeated if correction is not achieved.

Correction by rolling under general anesthesia is another nonsurgical option for this disorder. This has also been reported useful in a small number of horses with other forms of large colon displacements. This option is preferred if the horse is lame, or if there is marked large colon distention. Previous abdominal surgery may preclude it, however, as splenic adhesions may prevent successful correction of the displacement. The horse is prepared for short-term intravenous anesthesia. Sedation is given, followed by phentylephrine infusion as described previously. The horse is subsequently anesthetized and dropped into right lateral recumbency. Using a knee or two-handed fist, the clinician then shakes vigorously the abdomen in the region of the right flank, as the horse’s hind legs are being hoisted dorsally. If a hoist is not available, the horse is slowly rolled into dorsal recumbency while abdominal compressions are performed. With the hoist, the hind legs are elevated until the horse’s body reaches a 60-degree vertical position, while the clinician continues to vigorously shake the abdomen. After 1 or 2 minutes, the horse is replaced in right lateral recumbency. At this stage, some clinicians prefer to place the horse in left lateral recumbency, roll the horse into sternal position, and return it to right lateral recumbency. The procedure is repeated two more times. After the last manipulation, the horse is returned into left lateral recumbency for recovery. Between manipulations, the clinician may check the position of the colon. It is our experience that it is difficult to determine successful correction of the entrapment, either by ultrasonography or palpation, with the horse under general anesthesia. Therefore, we always recover the horse to determine if correction was achieved. Some clinicians prefer to follow immediately with surgical correction without recovery if it is suspected that correction was not achieved.

One author describes manipulation of the colons per rectum. With the horse in right lateral recumbency, the hand lifts the colons off the spleen as the horse is being turned to left lateral recumbency. The use of muscle relaxants is recommended when this procedure is used to relax the
Rectum. Rectal manipulation must be performed with extreme caution, as rectal tears represent a definitive risk of the procedure.157

Rectal palpation after manipulation often reveals that the colon is lateral to the spleen and has not completely resumed its normal position. Administration of fluids and calcium often results in complete correction within a few hours. Some horses may show mild abdominal pain after manipulation even though it is suspected that correction was achieved. This is probably a result of residual large colon distention or impaction, and it is usually responsive to analgesics.

**Surgical treatment**

If nonsurgical manipulations are unsuccessful, surgical intervention is indicated. Standing flank laparotomy or ventral midline celiotomy are options to consider. The advantages of the standing flank laparotomy are avoidance of general anesthesia, direct access to the problem, access to the nephrosplenic space for closure as an option for prevention of recurrence, and more rapid return to use of the horse. The major disadvantage, as is the case for nonsurgical manipulation, is if an incorrect diagnosis was made, precluding correction by this approach. The advantages of the ventral midline celiotomy are that it ensures successful correction, particularly in cases where the colons are located dorsal and cranial to the stomach, and it allows correction of other undiagnosed problems. The disadvantages include the need for general anesthesia, longer postoperative recovery, and increased cost.

**Standing flank laparotomy:** The horse is restrained in stocks with the tail bandaged and tied to avoid contamination of the incision. Sedation with xylazine, with or without butorphanol, is sufficient for most horses. After standard preparation of the surgical site, local anesthesia is performed. This can be accomplished with a paravertebral block,162 an L-block or a line block, taking care to add local anesthesia for placement of towel clamps. In our experience, the paravertebral block often requires additional local anesthetic in the distal aspect of the planned incision. Draping is routine, with the addition of a drape folded to form a pocket for support of the exterized bowel. The standard surgical approach for a flank laparotomy is midway between the last rib and the cranial aspect of the tuber coxae, starting approximately 2 cm above the palpable internal oblique muscle. In the standing horse, the modified grid approach is preferred, as the muscles will contain the intestinal contents after surgery. In the modified grid approach, the external oblique muscle is incised in vertical direction but the internal oblique and transverse abdominal muscles are bluntly separated along the course of their muscle fibers by finger traction. Additional topical application of anesthetic may be required before perforating the peritoneum. Once the abdomen is entered, the spleen and large colon are located. In our experience, it is easier to push the spleen down and under the large colon than to lift the large colon over the spleen. Once the colon is lateral to the spleen, it is gently pushed down into the ventral abdomen. Closure is routinely performed.

**Ventral midline celiotomy:** This approach is recommended for correction of nephrosplenic entrapment if nonsurgical management is unsuccessful and the surgeon is not comfortable with the flank approach or if there are clinical or clinicopathologic findings that indicate either the loss of intestinal integrity or the presence of another lesion. It is also used when a presumptive diagnosis is not possible because the small size of the patient precludes rectal palpation, or because excessive large colon distention is present. A routine ventral midline approach is performed, although to facilitate access to the nephrosplenic space the horse may be slightly rotated to the right. In the presence of excessive splenic congestion, or excessive weight of the colon, phenylephrine may be administered to reduce splenic size and facilitate correction. The base of the spleen is grasped, and the spleen is lifted and pushed medial to the colon, thus freeing it from the nephrosplenic space. The colon is subsequently cradled over the forearm and lifted out of the abdomen. Although there is often feed accumulation in the dorsal colon, evacuation is usually not necessary since the feed redistributes when the displacement is corrected. The colon is assessed for signs of devitalization. Rarely, a large colon resection will have to be performed.

Reported recurrence rates of nephrosplenic entrapment are between 7.5% and 8.5%.144,145 Considering this relatively low risk of recurrence, surgical intervention procedures for prevention of recurrence are not recommended after a first incidence. However, feeding and management practices should be carefully reviewed to minimize the risk of gas formation in the large colon and subsequent displacement.

**PREVENTION OF RECURRENCE**

Procedures that have been advocated for prevention of recurrence of left dorsal displacement of the large colon include closure of the nephrosplenic space, large colon colopexy, and large colon resection. The reader is referred to other sections (later) for reference to large colon resection and colopexy procedures.

Closure of the nephrosplenic space does not prevent migration of the large colon lateral to the spleen, or the occurrence of other forms of large colon displacement. The procedure can be performed through a flank laparotomy or though a minimally invasive laparoscopic approach.18,163,164 The flank approach is performed in the standing or laterally recumbent horse. The abdomen is entered either through a modified grid or laparotomy approach. The spleen and nephrosplenic ligament are identified, and the nephrosplenic space is verified to be free of intestine. Cruciate sutures are then placed between the ligament and the tip of the spleen, using a nonabsorbable suture such as 2-polypolypropylene in a cruciate pattern. Approximately 6 to 12 sutures are preplaced and tied. The abdomen is closed in a routine fashion. Alternatively, laparoscopic ablation of the renosplenic space can be performed in the standing horse165; this has been reported in five experimental animals. The procedure is performed using three laparoscopic portals and polyglactin 910 suture material in a simple-continuous pattern. Two series with small numbers of horses have reported long-term efficacy for this procedure.163,164

**Right Dorsal Displacement of the Large Colon**

This type of displacement is thought to be initiated by retroulsive movement of the pelvic flexure, with subse-
quent migration of the left colon cranially and then to the right abdominal quadrant, until the right ventral and dorsal colons are located between the cecum and the body wall (Fig. 36-14). The colon can also rotate on its long axis, resulting in variable degree of venous congestion.

**DIAGNOSIS**

The location of the colon at the time of examination is related to the clinical signs. When the colon is displaced cranially, all parameters are within normal limits, and abdominal pain is mild and intermittent. These horses may be comfortable when held off feed, with abdominal pain recurring when feed is reintroduced. These horses continue to pass small amounts of manure. On rectal palpation, there is no abdominal distention, but the examiner is unable to find the pelvic flexure. As the colon continues to migrate in a clockwise direction, the flow of ingesta is impaired, and a secondary impaction of the right dorsal colon may develop. Gas distention also becomes more significant, as does the associated abdominal pain. When a dorsal colon impaction develops, it is important not to mistake it for a pelvic flexure impaction, as continued medical treatment may result in rupture of the colon. This condition can be differentiated from a pelvic flexure impaction by the fact that the colon travels cranially to the right, and that the pelvic flexure cannot be identified. In right dorsal displacements, the cecum can be enlarged and filled with fluid.

Horses with right dorsal colon displacements are presented with mild to moderate abdominal pain. Depending on the degree of displacement, rectal palpation reveals absence of the pelvic flexure, presence of large colon lateral to the cecum, large colon distention, and right dorsal colon impaction. Nasogastric reflux may be present if there is large colon distention. Laboratory data are usually unremarkable, although a significant number of horses are presented with an elevated gamma-glutamyl-transferase, probably related to partial obstruction of the duodenum.

**TREATMENT**

When horses are presented early, with normal parameters, mild abdominal pain, and minimal to moderate large colon distention, medical therapy may be attempted. Intravenous fluids are administered and the horse is monitored for resolution of the distention and relocation of the large colon.

When the pain is severe, or there is marked large colon distention or a severe secondary impaction, surgical intervention is recommended. Although in some specific circumstances we have successfully corrected right dorsal colonic displacements via a standing flank laparotomy, a ventral midline celiotomy is preferred because of ease of exposure and correction.

At surgery, the pelvic flexure is identified, the large colon is exteriorized, and the displacement is corrected. When a severe large colon impaction coexists, the large colon is exteriorized at the pelvic flexure, but an attempt to correct the displacement is not made until the large colon has been evacuated, to avoid rupture during colonic manipulations. Although there is one report of successful treatment of a horse after intraoperative rupture during surgery,165 most of these cases are fatal.

**PROGNOSIS**

The prognosis for large colon displacement is excellent. Recurrence is possible, and we have had horses redisplace within 48 hours of the first procedure. In our opinion, it is important not to completely evacuate the large colon but to

---

**Figure 36-14.** Right dorsal displacement of the ascending colon (ventral views). A, The normal anatomic relationship of the ascending colon. B, The most common direction for a right dorsal displacement is migration of the pelvic flexure in a counterclockwise direction when viewed from the caudal and ventral aspect of the horse at the time of surgery. C, Although less common, the ascending colon may develop a right dorsal displacement characterized by a clockwise migration of the pelvic flexure when viewed from the caudal and ventral aspects of the horse at the time of surgery.
leave some ingesta. We also return these horses to feed within 8 hours of surgery, again to try to maintain bulk in the large colon.

**Nonstrangulating Volvulus of the Large Colon**

Nonstrangulating volvulus of the large colon is identified when the colon is rotated from 90 to 270 degrees along its long axis, a step that precedes the 360-degree large colon volvulus.

**DIAGNOSIS**

Horses with this type of displacement have a clinical presentation very similar to that of other simple large colon displacements; minimal cardiovascular compromise, mild to moderate abdominal pain, normal abdominocentesis, and mild to moderate large colon distention on rectal palpation. As in other displacements, medical management may be attempted. Horses that remain in pain or that have worsening of abdominal distention are candidates for surgical intervention. At surgery, the colon is replaced in its normal position.

As in all forms of large colon displacements or volvulus, prevention of recurrence should be considered. Colopexy and large colon resection are two procedures that are performed in an attempt to prevent recurrence. Usually these procedures are not recommended on a first-time occurrence, but should be considered for horses that have two or more displacements.

**Other Simple Obstructions of the Large Colon**

Congenital malformation of the large colon was reported as a cause of recurrent colic in a horse, and we have identified it in several horses. Resection of the colon oral to the malformation and anastomosis successfully resolved the problem.

Fibrosis and stricture of the large colon caused by focal fibrosis at the pelvic flexure was identified in three horses and corrected by transverse closure of a pelvic flexure enterotomy performed at the site of the fibrosis.

Pelvic flexure adhesions resulting in impaction were reported in a filly with peritonitis. Laparoscopic adhesiolysis was successfully performed to allow return of transit.

A massive duplication cyst of the ascending colon was reported in a 27-year-old mare with a history of recurrent colic and a pendulous abdomen. The cyst was successfully removed and the mare made an uneventful recovery.

We have observed defects in the mesentery of the large colon in several horses (see Fig. 36-8). The presence of the defect allows displacement or torsion of the colon upon itself, since it is no longer confined by the mesentery. The problem can be corrected by closure of the defects with the help of sutures.

**Large Colon Torsion or Volvulus**

Large colon volvulus is one of the most painful and devastating gastrointestinal problems in the horse (Fig. 36-16). Successful management depends on rapid referral and prompt surgical intervention. Without intervention, death occurs in a matter of hours in horses. The prevalence of large colon volvulus is increased in geographic areas with high concentration of brood mares. Risk factors include recent parturition, recent dietary changes, and recent access to a lush pasture.

**Diagnosis**

The history of horses with large colon volvulus varies depending on the rapidity and totality of the development of a complete volvulus. Some horses are presented with a history of chronic (more than 24 hours) colic that suddenly worsens to intractable pain; others are presented with an acute onset of uncontrollable pain. Initially, despite the severe pain, horses maintain normal cardiovascular parameters, and rectal palpation can be unremarkable. As time elapses, these horses develop progressive large colon distention and accompanying progressive cardiovascular collapse. In mares, the color of the vaginal mucosa changes and reflects the degree of compromise of the large colon. If untreated, horses with large colon torsion die of hypovolemic shock caused by abdominal compartment syndrome associated with the severe distention, by pooling of blood in the strangulated large colon, and by poor pulmonary expansion because of severe distention.

**Treatment**

The treatment of large colon torsion is surgical. However, during preparation for surgery, resuscitative measures should be initiated to increase circulating blood volume and
decrease abdominal pressure. Shock fluid therapy, including hypertonic saline, colloids, and crystalloids, needs to be initiated (see Chapter 3). Trocarization to relieve abdominal distention may improve lung expansion and venous return, and it can help support the horse during induction, until the colon can be exteriorized and decompressed.

In preparation for surgery, the horse can be tilted to one side to facilitate exteriorization of the colon and remove pressure on the caudal vena cava. Administration of intravenous lidocaine allows a decrease in the concentration of inhalant agents. A long ventral midline incision is performed to help in exteriorization of the colon. A more cranial approach is preferred, to facilitate exposure of the colonic base.

The direction of the torsion is best described in relationship to the position of the ventral colon, which obviates the need to describe it from the observer’s position. Thus, a dorsomedial volvulus indicates rotation of the right ventral colon medially and dorsally.\(^{170}\) Most are in a dorsomedial direction, and the location of the volvulus is at or proximal to the cecocolic ligament. Occasionally, a volvulus involving the splanchnic flexures is encountered.\(^ {171}\) Correction of the volvulus can be difficult, particularly if the colon is full or edematous; this places the colon, particularly the right dorsal colon, at risk for rupture during surgical manipulation. The ascending colon is exteriorized; if the colon is full or edematous and friable, a pelvic flexure enterotomy is performed to empty the colon prior to manipulation. To correct the volvulus, the surgeon, situated on the left side of the horse, places both hands in the abdomen around the base of the colon and gently manipulates the colon in a clockwise direction. The surgical assistant can facilitate manipulation by rotating the exteriorized portion of the colon in the same direction. Gas translocation and return of serosal color are indications that the colon is manipulated correctly. Once a 360-degree rotation has been achieved, the surgeon must ascertain that the volvulus is corrected, and that another rotation of the colon is not needed. This is accomplished by examining the normal position of the cecum and the normal position of the cecocolic ligament, and by ensuring by palpation that the mesenteric attachment of the right dorsal colon to the dorsal body wall is straight. Palpation of the duodenum cranial to the right dorsal colon is possible after the volvulus is completely corrected.

Once the colon has been returned to its normal position, the surgeon must decide between euthanasia, recovery of the horse without further intervention, colopexy for prevention of recurrence, and large colon resection. It is essential to involve the owner in the decision-making process, particularly if the colon is compromised, since the cost of further intervention and postoperative care can be significant. The surgeon must also understand that if the colon is not resected and the horse is recovered, it is unlikely that a second laparotomy will be an option. By the time clinical signs indicate that a second laparotomy with a possible large colon resection is warranted, the horse’s condition will have deteriorated to the point that the chances of survival after a resection will be poor. Several factors are useful to help the surgeon reach a decision. A critical one is the horse’s systemic condition both preoperatively and intraoperatively. A PCV above 50% (and increasing during surgery) associated with a decreasing total protein is a poor indicator of survival. An inability to maintain mean arterial blood pressure, despite the use of pressor agents, persistent hypoxemia, and persistent tachycardia during surgery, is also associated with poor survival. Examination of the colon can provide some additional information. Return of a normal pink serosal color after volvulus correction is a positive indicator, but it does not relate to mucosal viability; severe postoperative endotoxemia may still occur if the mucosa is devitalized. Visual examination of the mucosa made through a pelvic flexure enterotomy provides additional information.
The presence of dark red or black mucosa with no active bleeding is a poor prognostic indicator. Frozen sections allow calculation of the interstitial-to-crypt (I:C) ratio and percent loss of epithelium, which correlate well with survival. An I:C ratio of 3:1 or greater, or loss of greater than 95% of the epithelium, was associated with 95% death in one study. However, this requires personnel able to obtain and evaluate frozen sections. Other research tools that have been used to evaluate colonic viability include surface oximetry, fluorescein dye, and Doppler flow; none of these tools has gained popularity in a clinical setting (see Chapter 34).

The decision to perform a colon resection should also be based on the location of the volvulus. If the line of devitalized bowel is located distal to the cecocolic ligament, the outcome of a large colon resection is much more favorable, because resection of the affected bowel is possible. However, in most instances, the line of devitalization is located at the base of the colon oral to the cecocolic ligament; resection must be performed in a compromised portion of the bowel, which places the resection site at risk for dehiscence. Surgeons who are advocates of large colon resection for the treatment of large colon volvulus make a case that removing the majority of the diseased colon decreases the endotoxic load and therefore increases the likelihood of survival; in addition, removal of the large colon prevents recurrence of the condition. Surgeons who do not routinely perform large colon resections for large colon volvulus state that the procedure in itself has a high risk of complications, and that in most cases it does not result in removal of the entire diseased colon; in addition, the increased anesthesia time may be detrimental to the animal. These debates emphasize the complexity of the decision-making process in these cases, the importance of experience and familiarity with surgical techniques, and the influence of types of cases on the decision-making process. For example, horses that are referred quickly and have a short duration of illness seldom require a large colon resection.

Prognosis
Preoperative parameters indicative of poor survival include PCV greater than 50%, rectal temperature greater than 39.5 °C (102 °F), and a heart rate greater than 80 beats per minute. Intraoperative factors associated with a poor survival include black mucosal color, poor return of perfusion after detorsion, and an increasing PCV and decreasing total protein during surgery. Abdominocentesis is usually normal in horses with large colon volvulus; an increase in total protein in the abdominal fluid is associated with decreased survival. Abdominocentesis therefore does not provide information that will alter the decision for surgical treatment, and it has an increased risk of enterocentesis or injury to personnel because these animals are in severe pain.

Reported mortality for large colon volvulus varies from 56% to 65%. However, in one study, the short-term survival rate was 84%; this higher survival rate was thought to be related to a shorter duration of illness and faster intervention time. Although short-term mortality is high after surgical correction of large colon volvulus, a long-term probability of survival of .8 has been reported once discharge from the hospital occurred.

Right Dorsal Colitis
Right dorsal colitis is a specific type of ulcerative colitis observed in the right dorsal colon of the horse, specifically the aboral segment of the dorsal colon as it joins the transverse colon. The condition is recognized in association with administration of NSAIDs, and it has been reproduced experimentally by administration of phenylbutazone. Horses with nervous predisposition seem more prone to the development of the disease despite the administration of appropriate dosages of NSAIDs. Although NSAID administration is commonly associated with this condition, it has also been documented in the absence of NSAID administration.

Diagnosis
Clinical signs of right dorsal colitis can manifest as acute colic, endotoxemia, diarrhea, and even death. The disease is more common in the chronic form, where horses are presented for weight loss, hypoproteinemia, intermittent signs of colic, and intermittent diarrhea. The diagnosis of right dorsal colitis is based on anamnestic information, particularly related to NSAID administration, and ruling out other causes of weight loss, hypoproteinemia, and diarrhea. Diagnostic ultrasonography of the right dorsal colon may help identify the thickened colon (Fig. 36-17). More recently, scintigraphy with radiolabeled white blood cells has been described to diagnose the condition.

Treatment
Medical management is recommended for the initial treatment of right dorsal colitis. This includes discontinuation of NSAIDs, dietary modifications, anti-inflammatory drugs, intestinal protectants, and metronidazole. Dietary modifications are important to help control the signs of colic.

In cases of protracted colic, or when intermittent colic is so frequent as to prevent the horse from maintaining itself, surgical exploration may be recommended. At surgery, the right dorsal colon feels markedly thickened, and it may be strictured with scar tissue (Fig. 36-18). Once the disease is

Figure 36-17. Sonographic image of the right dorsal colon showing marked thickening of the colonic wall in a horse with right dorsal ulcerative colitis associated with phenylbutazone toxicity. The image was obtained using a 7.5-MHz probe directed into the 10th right intercostal space. 
identified at surgery, treatment options include right dorsal colon bypass, resection of the affected portion of the colon, large colon resection, or large colon resection and bypass. Bypass of the affected area of the large colon is performed by exteriorizing the large colon on a colon tray. The small colon is then exteriorized and a 20- to 30-cm side-to-side anastomosis between the right dorsal colon (oral to the lesion) and the small colon approximately 1 m distal to the transverse colon is performed (Fig. 36-19). When this procedure is performed, transient diarrhea has been observed. This procedure does not remove the affected portion of the colon, so the patient can continue to suffer from weight loss and hypoproteinemia until the colitis has resolved. Resection of the affected colon through a 16th rib resection has been reported in one horse (Fig. 36-19). When this procedure is performed, transient diarrhea has been observed. This procedure does not remove the affected portion of the colon, so the patient can continue to suffer from weight loss and hypoproteinemia until the colitis has resolved. Resection and end-to-end anastomosis is possible only if the lesion does not extend too far aborally. In cases of severe right dorsal colitis with stricture of the right dorsal colon, large colon resection and anastomosis in a side-to-side fashion can be performed to restore intestinal transit. However, complete removal of the ulcerated area would not be possible with this approach. Another approach, which has not been described for the treatment of this condition, would be to amputate the large colon, particularly the dorsal colon, as far aborally as possible, and to perform an end-to-side anastomosis between the right ventral colon and the small colon. This approach has been reported for the management of nonfunctional dorsal colon lesions in two horses.

Mural Infarction (Thromboembolic Colic)

Compromise to the mesenteric vasculature without evidence of strangulation has been described in association with arteritis resulting from Strongylus vulgaris larval migration, or in horses with severe colitis and coagulopathies (Fig. 36-20). Cases of larval arteritis can be acute (with signs of ischemic bowel disease and peritonitis) or chronic (with signs of recurrent colic and weight loss). Horses with acute thromboembolic colic demonstrate significant changes in their abdominocentesis, consistent with those seen with peritonitis; horses with recurrent colic often have a normal abdominocentesis.

In acute cases, the decision for surgical intervention is based on the signs of colic and the presence of peritonitis. At surgery, mural infarction is identified, and if possible, resection of the affected segment of intestine is performed. Careful palpation of the cranial mesenteric artery should be performed; identification of severe enlargement, aneurysm, or abscessation is an indication for a guarded to poor prognosis. A regular systemic deworming program should be instituted as part of the postoperative care.

When horses with colitis show acute signs of abdominal pain and abdominal distention, thromboembolic colic and necrotizing colitis should be suspected. Many of these horses have extensive lesions that preclude surgical intervention. In addition, their systemic status, as a result of the primary colitis, makes them poor surgical candidates.
Other Strangulating Lesions of the Large Colon

Other strangulating lesions of the equine large colon that have been reported include incarceration in the epiploic foramen\textsuperscript{48} or the gastrosplenic ligament\textsuperscript{18,1}; large colon intussusception\textsuperscript{182,183}; and volvulus associated with abnormal mesenteric bands or defects.\textsuperscript{35,184} Surgical intervention is dictated in these cases by the increasing degree of abdominal pain, abnormal rectal palpation, and abdominocentesis indicative of intestinal compromise. Resection and anastomosis of the affected colon is required to correct these conditions.

Surgical Procedures

Large Colon Enterotomy

The most commonly performed procedure in the large colon is pelvic flexure enterotomy for evacuation of the large colon. Enterotomy procedures are also performed for removal of foreign bodies, usually in the right dorsal colon. Finally, right ventral colon enterotomy is used to access the cecum in cases of cecocolic intussusceptions.

Pelvic flexure enterotomy and large colon evacuation: For this procedure, the large colon is exteriorized and placed on a colon tray (Enterotomy table, Kimzey Metal Products, Woodland, Calif), either on the left side of the horse or caudally between the horse's hind legs. If a colon tray is not available, the colon is best exteriorized between the hind legs. Some surgeons place the end of the laparotomy drape onto the tray to create a shelf for the colon to rest on. The enterotomy drape is then placed on top of the laparotomy drape and secured with towel clamps. The colon tray is angled at about 20 degrees. A modified trashcan with an ingesta strainer and a liquid outflow hose is used in some clinics to collect and evacuate the contents of the colon\textsuperscript{185} (Fig. 36-21). Alternatively, the end of the tray can be positioned over a disposal system built into the surgery room (Fig. 36-22). In anticipation of colonic evacuation, a lavage system should be established. This can be done by using two garden hoses, or one hose with a Y-connection. One hose is used for intraluminal lavage and evacuation of the colon, and the other for extraluminal lavage, using warm water (37° C [98.6° F]).\textsuperscript{185} If these are not available, stomach tubes, buckets, and pumps are used.

A full-thickness, 8- to 12-cm incision is made on the antimesenteric border of the pelvic flexure.\textsuperscript{186} One hose is inserted and gently advanced into the colon, while the other is used to continuously lavage the serosal surface to prevent fecal contamination. During the evacuation procedure, it is useful to lift the colon and ensure that the underside is lavaged as well. With sterile technique, an assistant helps to feed the hose into the colon and massage its contents. Although a modified colon tray has been described to evacuate the colon, it is not deemed necessary by most surgeons.\textsuperscript{187} At this time, if colonic evacuation is performed as part of the correction of a large colon torsion, an intestinal biopsy can be collected. Closure of pelvic flexure enterotomies is performed using 2-0 absorbable suture material in two layers: a simple-continuous seromuscular layer followed by a Lembert or a Cushing pattern.\textsuperscript{188} The colon is rinsed thoroughly with sterile saline and replaced in the abdomen.

Figure 36-21. Modified colon tray used to evacuate the large colon. In this case, the contents are collected in a modified trash can with a strainer that allows fluids to be evacuated through the drainage system.

Enterotomies in the right dorsal or ventral colon are performed after the colon has been draped off from the main surgical field. In the ventral colon, enterotomies are performed between teniae, since the fibrous nature of the teniae precludes successful inversion during suturing. In the dorsal colon, the location of the enterotomy is not as critical. Enterotomies performed at these sites are more likely to suffer from postoperative luminal hemorrhage; a full-thickness closure (simple-continuous or Connell) is therefore performed on the first layer to achieve better hemostasis.\textsuperscript{83} A Lembert or Cushing pattern is used as the second layer.

A modified Heineke-Mikulicz technique for pelvic flexure enterotomy closure has been described in two horses with extensive stricture of the large colon.\textsuperscript{167} A longitudinal incision was centered over the stricture and closed using a transverse closure, effectively increasing the diameter of the colon at that site.

Large Colon Resection

Resection of the large colon is performed for removal of full-thickness mural defects in the large colon. Causes include strangulation, infarction, thromboembolic disease, neoplasia, and scar tissue formation.\textsuperscript{167,181,183-195} Removal of 50% to 95% of the large colon has been described.\textsuperscript{196-200} Techniques for resection of the large colon

Large Colon Resection

Resection of the large colon is performed for removal of full-thickness mural defects in the large colon. Causes include strangulation, infarction, thromboembolic disease, neoplasia, and scar tissue formation.\textsuperscript{167,181,183-195} Removal of 50% to 95% of the large colon has been described.\textsuperscript{196-200} Techniques for resection of the large colon

---
include resection and end-to-end anastomosis, and resection and side-to-side anastomosis. End-to-end procedures are performed for removal of the colon up to 10 to 12 cm from the cecocolic ligament.\textsuperscript{172} When resection of the colon closer to or proximal to the cecocolic ligament is required, a side-to-side technique is preferred because the end-to-end technique exerts too much tension on the anastomotic site, placing it at risk for dehiscence. In our experience, it is important to ensure that apposition of the colons in an end-to-end fashion is achieved without tension, and this requires that a substantial amount of colon remain distal to the cecocolic fold.

For a resection and end-to-end anastomosis, the colon is exteriorized on a colon tray and draped off; the cecum is replaced in the abdomen. All ingesta are massaged into the segment to be removed. If the colon is full, a pelvic flexure enterotomy is performed to evacuate the colon; care must be taken to remove all ingesta and water from the right dorsal and ventral colons to minimize contamination during the resection. For the resection, a site is chosen that is located in the healthy part of the colon (if possible) and that is easily held by the assistant surgeon without tension on the mesentery.\textsuperscript{172} The colon is positioned to expose the right colic artery and the colic branch of the ileocolic artery within the mesocolon; the colonic vessels are isolated by blunt finger dissection and double-ligated using 1 polyglactin 910 (Fig. 36-23). Alternatively, two double rows of staggered staples (TA-90 Premium, United States Surgical Corp, Norwalk, Conn) are applied across the mesocolon, followed by a third double-staggered row 4 cm distal. The mesocolon is transected between the proximal and distal staple lines. Hemostasis is verified and any bleeding vessels are ligated. The right ventral colon is transected in a line transverse to its long axis, whereas the dorsal colon is transected at a 30-degree angle to its long axis, with the antimesenteric border shorter so that the diameters of the colons are similar (Fig. 36-24, A). In the original description of the procedure, a V-shaped stoma was then created between the mesenteric border of the dorsal and ventral colons using an inverting linear anastomotic instrument (GIA Premium 55, United States Surgical) reinforced with a double-layer, simple-continuous pattern. This step was omitted in later descriptions of the procedure.\textsuperscript{201} Starting at the mesenteric border and suturing from the lumen, the colons are apposed with a double-row, simple-continuous pattern using 0 polydioxanone or Vicryl. The second layer should be full thickness to achieve hemostasis (see Fig. 36-24, B). Once the mesenteric portion of the anastomosis is completed, suturing is approached from the serosal side, and the colons are apposed using a double layer, starting with a Connell followed by a Lembert pattern (see Fig. 36-24, C). The colon is lavaged and replaced in the abdomen.

For a side-to-side anastomosis, the site of resection is usually more proximal, at the cecocolic ligament or oral to it. The colon is exteriorized to the left of the horse on a colon tray and the colonic vasculature is transected as previously described. The stoma is then created before the resection, taking advantage of the weight of the colons to facilitate exposure of the anastomotic site. The site for creation of the stoma is identified, taking care to end it just proximal to colonic vessel ligation, so that a blind sac is not formed. A three-tier side-to-side stoma is created; the first layer apposes the seromuscular layers of the colons using 1 polyglactin 910 in a Lembert or Cushing layer for a length of 20 cm (Fig. 36-25, A). A full-thickness incision is made in each colon and a full-thickness simple-continuous circumferential closure interrupted at 180 degrees is made to create the stoma (see Fig. 36-25, B and C). The upper layer is then apposed using a Cushing or Lembert pattern (see Fig. 36-25, D). Alternatively, the stoma can be created using stapling instrumentation. This may minimize contamination, but it may not be possible if the colons are too thick and edematous as a result of the underlying disease process. For an adequate-size stoma, the stapling instrument is fired twice if the ILA-100 or the GIA-90 is used, and three times if

---

Figure 36-23. The ascending colon is placed on a colon tray with the vessels facing uppermost. The colonic vessels are isolated by blunt finger dissection and double- or triple-ligated before transection (inset).
the GIA-55 is used (the staples for the latter are smaller). Staple lines should be oversewn. Once the staples have been applied, the down layer cannot be approached for oversewing. This layer should therefore be performed first, before application of the stapling instrument. Once the stoma is created, the colons are resected, starting with the ventral colon, taking care to resect them at the site of colonic vessel ligation. The lumens are closed using a full-thickness simple-continuous or Connell pattern, and oversewn with a Lembert or Cushing pattern (Fig. 36-26). The resected colons are lavaged and replaced in the abdomen. Although resection of the large colon has been reported using stapling instrumentation, this is usually not possible after correction of large colon torsion, since the intestinal edema and congestion do not allow proper closure of the instrument and adequate formation of the staples.

An early method of large colon resection has been described that uses a luminal approach to create the side-to-side anastomosis, followed by closing the ends of the colons.\(^{198}\) The technique described earlier for end-to-end resection represents a modification of this technique.

Successful bypass of the right dorsal colon for the treatment of large colon volvulus has been described in one horse.\(^ {180}\) In that report, the large colon was judged to be nonviable after correction of a large colon volvulus. The right dorsal colon was transected as far distally as possible within the abdomen, using a TA-90 stapling instrument, and the suture line was partially oversewn. The right ventral colon was transected 10 cm from the cecocolic ligament, and an end-to-side anastomosis between the right ventral colon and the descending colon was performed using a double-layer inverting pattern. Two mild episodes of colic and diarrhea for 1 week were the reported complications. In a similar fashion, anastomosis of the right ventral colon to the descending colon was performed using a double-layer end-to-side anastomosis in a miniature pony reported.\(^ {179}\) A two-layer hand-sewn end-to-side anastomosis was performed between the right ventral colon and the small colon. One episode of colic successfully treated with medical therapy was the only postoperative complication encountered in this case.
The amputated ends of the large colon are closed side-to-side resection at or proximal to the cecocolic fold. The lumens are closed using a full-thickness simple-continuous or Connell pattern, oversewn with a Lembert or Cushing pattern.

**COMPLICATIONS**

Complications from large colon resection are usually a result of the primary disease. They include persistent endotoxemia and peritonitis caused by continued bowel devitalization. This is because the site of torsion is usually at or proximal to the site of resection, so that some portion of compromised large colon cannot be removed. It is therefore essential for the surgeon to remove as much of the devitalized colon as possible. In our experience, this requires a side-to-side resection at or proximal to the cecocolic fold. Even then, a segment of devitalized colon may remain in the abdomen, leading to subsequent complications. Most horses that succumb to endotoxemia and peritonitis do so within 3 to 7 days postoperatively after requiring considerable intensive care. In contrast, survivors see an improvement in clinical signs within 24 hours of the procedure.

Postoperative pain is common in horses after large colon resection. It is a painful procedure, even in normal horses. Administration of NSAIDs, lidocaine, and opiates can help alleviate the pain.

Signs of endotoxemia are common after large colon resection for large colon volvulus. Signs include fever, tachycardia, injected mucous membranes, dehydration, and hypoproteinemia. Signs of large colon ileus, such as distention, which can be quite severe, may also occur. Supportive care with fluids, plasma, and antiendotoxin modalities are important (see Chapter 2). Horses should be monitored for signs of postoperative hemorrhage, which is more prevalent with large colon procedures and occasionally requires a blood transfusion.

Postoperative diarrhea is commonly observed after large colon resection, because of mucosal damage or the reduced surface area available for fluid absorption. The diarrhea is usually self-limiting and resolves within a few days if it is not of infectious origin. However, isolation procedures should be followed as dictated by hospital protocol, and infectious diseases should be ruled out.

Horses with successful resection of the large colon usually regain normal fecal consistency within 5 to 7 days. Because of the decreased surface area available for digestion and water absorption, these horses have increased water and phosphorus requirements and require a highly digestible diet.

**SMALL COLON**

**Anatomy**

The transverse colon is the continuation of the right dorsal colon. It begins at the level of the 17th or 18th thoracic vertebra where the right dorsal colon narrows significantly in diameter as it turns medially.1,2 The transverse colon is short and passes from right to left, cranial to the cranial mesenteric artery. It is connected dorsally to the pancreas, to the dorsal aspect of the abdominal cavity, and by a short transverse mesocolon to the root of the mesentery. These attachments prohibit visualization of the transverse colon during a celiotomy. To the left of the root of the mesentery, the transverse colon continues as the descending colon, also known as the small colon. The small colon occupies the left caudal dorsal quadrant of the abdominal cavity. The small colon is approximately 3.5 m long and maintains a 7- to 10-cm width throughout its entire length. It is suspended by a long descending mesocolon, which allows good surgical access to all but the most proximal and distal portions of the small colon. The descending mesocolon originates from the left surface of the root of the mesentery and continues caudally attached to the dorsal body wall until it turns into the mesorectum at the pelvic inlet.1,2 The mesocolon often contains a significant amount of fat. The small colon is attached to the terminal duodenum by the duodenal colic fold, which is an important surgical landmark when exteriorizing the proximal jejunum. The small colon has two longitudinal muscular bands called teniae, one within the mesocolon and the other on the antimesenteric border. Contractile activity of the longitudinal bands and circular muscle produce sacculations in which feces are formed into fecal balls.202

The vascular supply to the small colon is derived from the caudal mesenteric artery with anastomoses cranially from the cranial mesenteric artery and caudally from the middle and caudal rectal arteries. The caudal mesenteric artery divides into two major branches, the left colic artery and the cranial rectal artery, with the left colic artery supplying the proximal three fourths of the descending colon and the cranial rectal, the distal one fourth.203 The left colic artery branches into four to eight arcuate arteries, each dividing into a cranial and caudal branch, which run parallel to the small colon to anastomose to adjacent arcuate arteries (Fig. 36-27). The cranial rectal artery gives off similar arcuate vessels. These anastomosing arcades running parallel to the bowel are called marginal arteries. A secondary anastomosing arcade branching off the marginal arteries runs between the marginal artery and bowel wall, sending off short branches that perforate the mesenteric teniae, and long branches that anastomose in the antimesenteric teniae with
Horses with small colon disease make up 1.9% to 18.5% of horses admitted to referral centers with signs of gastrointestinal disease. Pathology of the Small Colon
Horses with small colon disease make up 1.9% to 18.5% of horses admitted to referral centers with signs of gastrointestinal disease. The incidence of small colon disease is approximately 4% in horses undergoing surgical treatment for colic. Arabian Horses, ponies, and American Miniature Horses are more predisposed to diseases of the small colon. Female horses and horses older than 15 years are more likely to have small colon disease, whereas horses younger than 5 years are less likely to be affected. Diseases may be broken down into congenital abnormalities, such as atresia coli and colonic aganglionosis; simple obstructions, including fecal impaction, fecoliths, phytobezoars, trichobezoars, enteroliths, and retained meconium; vascular lesions, including intramural hematomas and mesocolon tears; strangulating lesions such as lipomas, internal hernias, and volvulus; and neoplasia. (Distal iatrogenic tears, described as rectal tears, although frequently occurring in the small colon, are discussed in Chapter 37.)

**Simple Obstructions**

**Fecal Impaction**

Horses with small colon fecal impaction represent 1.9% to 2.5% of all those admitted for signs of abdominal pain. Fecal impaction has been reported to be the most common pathologic condition of the small colon except in regions with a high incidence of enterolithiasis. Suggested risk factors are poor dentition, poor-quality hay, lack of water, parasite damage, lack of exercise, submucosal edema, and motility problems. The fall and winter seasonal predilection observed in some studies may be the result of inadequate water consumption or change of feed. Older horses (older than 15 years), American Miniature Horses, and ponies were at an increased risk in several studies, but age and breed were not significant risk factors in other reports.

**Diagnosis**

The most common clinical signs, in order of decreasing frequency, are abdominal pain, decreased manure production, diarrhea, anorexia, fever, straining to defecate, and depression. The colic is initially manifested as mild abdominal pain with a slow progression of signs. The heart rate can be mildly to moderately elevated. Leukopenia with a left shift is not uncommon in horses with small colon feed impactions, whereas serum biochemical and peritoneal fluid values are typically within normal ranges. The diagnosis can frequently (i.e., in 75% to 83% of cases) be made by palpation of the impaction per rectum. Other palpation findings that have been noted are distention of the large intestine and cecum, edematous or rough rectal mucosa, and neoplasia. (Distal iatrogenic tears, described as rectal tears, although frequently occurring in the small colon, are discussed in Chapter 37.)

**Medical and surgical interventions often carry a good to excellent prognosis.**
associated with small colon impaction may predispose horses to colitis.209,211

**MEDICAL TREATMENT**

Most fecal impactions are initially managed medically. The goal is to improve hydration, stimulate motility, and soften the impaction. All feed should be withheld and the impaction hydrated. This is accomplished through administration of both intravenous fluids (two to three times the maintenance volume) and oral fluids (2 to 4 L every 4 to 6 hours).209,211 Oral fluids have the additional benefit of initiating a gastrocolonic reflex, whereby gastric distention stimulates contractile activity of the colon.206,210 Oral laxatives such as mineral oil, dioctyl sodium sulfosuccinate, or magnesium sulfate administered by nasogastric tube are commonly used to soften the impaction. Mineral oil (5 to 10 mL/kg every 12 hours) is frequently used to lubricate the impaction, and its presence in the peritoneum is an indication that the obstruction is incomplete. Magnesium sulfate administered to normal horses at 1 g/kg in 6 L of water has been shown to increase total weight of fecal excretion and fecal water excretion compared with administration of a lower dose (0.5 mg/kg), whereas DSS (50 mg/kg in 6 L of water) failed to increase the weight of feces excreted or fecal water excretion.114 Magnesium sulfate can be administered once daily for 2 to 3 days if the horse is well hydrated. Magnesium toxicity appears more likely to develop in dehydrated horses or in horses treated simultaneously with DSS.46,213 Flunixin meglumine (0.25 mg/kg three times a day, or 1.1 mg/kg twice a day IV) is administered to treat endotoxemia and to control pain if necessary. Antibiotics may be indicated in horses with signs of septicemia, severe leukopenia, or concurrent diarrhea. Other antiendotoxin therapy such as polymyxin B (2000 to 6000 U/kg IV) or *Salmonella typhimurium* antiserum may also be beneficial.209 Standing enemas may be used in selected cases to break down impactions in the distal small colon, but extreme caution should be exercised to avoid producing a rectal or small colon tear.202,207,209 The horse should be adequately sedated and restrained, and epidural anesthesia should be performed. The enema should be administered, without pressure, by gravity flow. Because of the potential for iatrogenic trauma, some authors do not recommend enemas for treatment of small colon impactions.202,204,209

**SURGICAL TREATMENT**

Surgical management is indicated in horses with increasing abdominal pain, increasing abdominal distention, or changes in abdominal fluid indicating deterioration of the bowel. In some horses, large colon displacement or volvulus may occur secondary to gas distention proximal to the impaction. The small colon is exteriorized through a ventral midline celiotomy. The most common technique to relieve the impaction is intraluminal lavage with warm water introduced by stomach tube inserted through the anus by an assistant using aseptic technique. The surgeon manipulates the tube to the distal extent of the impaction and then manually clamps off the small colon lumen and to the end of the tube to allow water distention around the distal extent of the impaction. Extraluminal massage is used to gently work the fluid into the feces to break up the distal portion of the impaction. These manipulations are repeated working oral until the impaction is relieved. To decrease mechanical damage to the serosa during the massage, sterile carboxymethylcellulose should be placed on the small colon that is being massaged.209 In some cases, when the small colon impaction cannot be relieved by intraluminal lavage with external massage, a small colon enterotomy is performed in the antimesenteric teniae adjacent to the impacted small colon, and lavage is used to evacuate the impacted fecal material through the enterotomy (see “Small Colon Enterotomy,” p. 471). In rare cases, mural ischemia or thrombosis of the mesenteric vessels necessitates resection of a segment of small colon (Fig. 36-28) (see “Small Colon Resection and Anastomosis,” p. 472). Ingesta in the large colon should be evacuated through a pelvic flexure enterotomy to prevent postoperative impaction in the edematous and inflamed small colon.

Postoperatively, horses should be started back on feed slowly. Feeding a complete pelleted diet for several weeks may help prevent reimpaction.207 Extension of perioperative use of antibiotics (24 hours postoperatively) to therapeutic use of antibiotics (5 to 7 days postoperatively) is made on a case-by-case basis, dictated by surgical findings and clinical and laboratory evaluation of the horse. In most cases, antibiotics can be discontinued within 24 hours.

**PROGNOSIS**

Survival after medical therapy has been reported to be good to excellent (72% to 100%), and survival after surgical therapy has been reported to be fair to good (47% to 75%).153,204,208 The most common complications after medical or surgical therapy are diarrhea and jugular thrombocephalitis.153,204,208 Other complications seen are fever, laminitis, peritonitis, incisional infection, incisional hernia, recurrent colic, recurrent impaction, and small colon adhesions.153,204,208 Surgical cases in which the colon was not evacuated at surgery are more likely to develop postoperative pain.209 Fecal cultures for *Salmonella* are positive in up to 43% of surgically treated horses.204,208 Postoperative antibiotic therapy may increase the risk of these horses developing salmonellosis by altering gastrointestinal flora.202,207

Intestinal Concretions and Foreign Bodies

Enterolithiasis

The small colon is the site of the obstruction in approximately 45% to 57% of horses with enteroliths, accounting for up to 35% of all small colon diseases in certain geographic regions such as California. The etiology was discussed in the large colon section.

DIAGNOSIS

Horses commonly exhibit multiple episodes of mild colic, most likely from intermittent obstruction in the large colon or proximal transverse colon, before the enterolith enters the small colon. Once the enterolith enters the small colon, the clinical course is determined by the size of the enterolith. Although some are small enough to pass through the small colon without clinical problems, it is not uncommon for the enterolith to become wedged within the lumen of the transverse or small colon, usually in a more proximal segment. Horses typically show signs of increasing abdominal pain, although in some horses rupture occurs with little or no observed abdominal pain. On rectal examination, the large colon may have palpable gaseous distention. Peritoneal fluid analysis should be monitored closely. It is not uncommon for enteroliths wedged in the transverse and small colons to cause pressure necrosis at the area of obstruction. A slight elevation in peritoneal fluid protein may indicate the need for surgical intervention. Radiographs successfully diagnose small colon enteroliths in approximately 40% of horses, as compared with 83% of horses with large colon enteroliths. Surgical exploration is based on signs of increasing pain, increasing abdominal distention, peritoneal fluid changes, and radiographic evaluation. The most common site of gastrointestinal tract rupture in horses with enteroliths is in the descending colon. Since some horses show little pain prior to rupture, careful monitoring of horses with suspected enterolithiasis is critical to ensure timely surgical intervention.

TREATMENT

Treatment is surgical removal through an antimesenteric small colon enterotomy or retropulsion and removal through an enterotomy in the dorsal colon or pelvic flexure. Horses are started on broad-spectrum antibiotics and a ventral midline celiotomy is performed. Retropulsion with lavage can be accomplished by inserting a hose up the rectum. Alternatively, a hose can be inserted through a pelvic flexure enterotomy and advanced to the transverse or small colon obstruction, and lavage can be used to distend the small colon on the oral side with the anal side being clamped off manually. The most important aspect of these techniques is letting the water gradually distend the bowel to aid in dislodging the enterolith. Pressure necrosis can make the bowel wall susceptible to rupture.

When enteroliths are removed by a small colon enterotomy, it is important to ascertain if there are additional enteroliths located proximally. In one study, 45% of horses with enterolithiasis had multiple stones. Particular attention should be paid to the right dorsal and transverse colon, since it may be difficult to palpate a small enterolith if there is an appreciable amount of ingesta in the large colon. Commonly, a pelvic flexure enterotomy is performed prior to the small colon enterotomy to evacuate ingesta from the large colon. This also will decrease the amount of fecal material passing over the small colon enterotomy site in the immediate postoperative period.

PROGNOSIS

Horses recovering from surgery for enteroliths in the small colon have a good to excellent prognosis (up to 92.5%). In most cases, antibiotics are discontinued 24 hours after surgery. It is not uncommon for the area where the enterolith was wedged in the small colon to slough some of the mucosa after surgery with absorption of endotoxin. NSAIDs should be continued for 3 to 5 days, depending on the extent of intestinal insult found at surgery. Complications noted after surgery are diarrhea, incisional infection, incisional hernia formation, positive fecal cultures for Salmonella, laminitis, septic peritonitis, and adhesions. Dietary and management changes have been discussed in the large colon section. Recurrence has been identified in 7.7% of cases.2

Fecaliths, Phytobezoars, Trichobezoars, Phytotrichobezoars, and Phytoconglobates

Fecaliths are inspissated balls of fecal material that form as a result of poor-quality diet, poor mastication, or reduced water intake. They have been reported to occur in approximately 7% of horses with small colon disease, but they probably make up a larger proportion of small colon disorders in regions where enteroliths are not common. Small colon fecaliths have a tendency to occur in young (less than 1 year old) and older (more than 15 years old) horses. Ponies, American Miniature Horses, and mixed-breed horses appear to be at an increased risk. Phytoconglobates are concretions of matted plant residues formed into balls. Bezoars are combinations of concretions of magnesium ammonium phosphate and plant material (phytobezoars) or hair (trichobezoars). Concretions composed of hair and plant material are called phytotrichobezoars. Obstruction caused by ingestion of fibrous, nondigestible material occurs most commonly in horses less than 3 years old and in horses with poor dentition. Fecaliths, phytobezoars, trichobezoars, and phytotrichobezoars form in the large colon and become symptomatic as they pass into the small colon and obstruct the lumen. Clinical signs are similar to those of foreign body obstructions. Treatment is surgical removal by small colon enterotomy, or by retropulsion into and removal from the large colon.

Foreign Body Obstructions

Obstruction of the small colon with foreign objects has been reported in several studies. The obstructing objects include rubberized fencing and nylon tires, baling twine, rope, disposable plastic sleeves, feed sacks, and cloth material. Young horses (less than 3 years of age) with indiscriminate eating habits are thought to be more likely to develop these foreign body impactions. Poor pasture may also contribute to consumption of inappropriate material.

Signs reported are similar to those seen in other small colon obstructions, such as getting up and down, stretching,
anorexia, and scant passage of feces. Walking backward and dog sitting have also been reported. The heart rate can be normal to markedly elevated. Depending on the configuration of the foreign body, the obstruction may be incomplete, allowing some passage of gas and ingesta, or complete, producing tympany and impaction proximal to the obstruction. With complete obstruction and proximal distention, the abdominal pain becomes more severe. Nasogastric reflux from the distended large intestine compressing the proximal small intestine may occur. In horses with a distal obstruction, tenesmus is common. On rectal palpation, horses frequently exhibit marked abdominal straining, have a large intestine distended with gas and feces, and have no fecal balls in the small colon. In some cases, the obstructing mass is palpable per rectum, although frequently the obstruction is in the proximal small colon out of reach of rectal palpation.

Foreign bodies may produce pressure necrosis of the wall of the small colon where they are lodged. In these cases, peritoneal fluid analysis reveals an elevated protein concentration and sometimes an increase in nucleated cell count. Treatment is surgical removal via a small colon enterotomy in the majority of cases, or through retroperitoneal intubation into the dorsal colon if the obstruction is at an inaccessible portion of the proximal small colon or transverse colon.

**Meconium Impaction**

Meconium is a mucilaginous material in the intestine of the fetus, composed of intestinal glandular secretions, bile, epithelial cells, and swallowed amniotic fluid. Typically, peristaltic activity moves meconium into the colon or rectum before birth, and it is evacuated between 3 and 24 hours after birth. Meconium is considered retained if the foal makes frequent attempts but fails to produce meconium by 12 hours of age. Retained meconium is the most common cause of colic in the neonate. Meconium impaction accounted for 0.8% of all cases of equine colic in one study, with a mortality rate of 15.2%. Ingestion of colostrum promotes gastrointestinal activity and may have a laxative effect to aid in expulsion of meconium from higher up in the colon. Delayed ingestion of colostrum, and conditions that compromise the foal such as asphyxia, dystocia, prematurity, low birth weight, and dehydration are thought to be risk factors for meconium impaction. Males are more commonly affected, most likely because of their smaller pelvic size.

**DIAGNOSIS**

Clinical signs begin with restlessness, tail switching, straining to defecate, and disinterest in nursing. As the condition progresses, foals develop signs of more severe colic, such as lying down and getting up, rolling, lying upside down, and abdominal distention. The diagnosis is based on clinical signs, historical absence of meconium passage, and detection of a firm mass on digital rectal palpation. Plain and retrograde contrast abdominal radiography can show tympanic bowel and often dense meconium. Ultrasonography may show a distended large colon. The differential diagnosis is ruptured bladder, atresia coli, ileocolonic aganglionosis, and enteritis.

**TREATMENT**

The preferred method of treatment is multiple administration of enemas along with intravenous fluids and nasogastric administration of laxatives for more persistent obstructions. Commercially available phosphate enemas (Fleet enemas, CB Fleet Co, Inc, Lynchburg, Va) are frequently used. More recently, 4% acetylcysteine enema solutions have been recommended for treatment of retained meconium. The compound cleaves the disulfide bonds in the mucoprotein molecules and decreases the tenacity of the meconium. The 4% solution can be made by mixing 40 mL of a commercial 20% acetylcysteine solution (Ben Venue Inc, Bedford, Ohio) with 160 mL of water. Because the activity of acetylcysteine increases with increasing pH (pH 7 to 9), 20 g (1 1/2 level tablespoons) of NaHCO₃ powder (baking soda) is added to the 200 mL of dilute solution. Alternatively, 8 g (1 packed tablespoon) of a powdered form (N-acetylcysteine, Sigma Chemical Co, St. Louis, Mo) can be mixed with 200 mL of water to which 20 g of NaHCO₃ is added. The foals are restrained, sedated with diazepam (0.2 to 0.4 mg/kg IV), and placed in lateral recumbency. A 30-Fr Foley catheter with a 30-mL bulb is inserted about 2.5 to 5 cm into the rectum. The balloon is slowly inflated, using care to not damage the rectum. Between 100 and 200 mL of the 4% solution is administered slowly by gravity flow and retained for 30 to 45 minutes. This can be repeated up to three times over a 24-hour period. The prognosis after acetylcysteine enemas has been reported to be excellent. High meconium retention can be treated with intravenous fluids and mineral oil administered by nasogastric tube. Surgery should be performed only on foals that have failed to respond to aggressive medical therapy. Postoperative complications involving adhesion formation are not uncommon after gastrointestinal surgery of neonates. In one study, 8 of 28 foals with meconium impactions failed to respond to medical therapy and required surgery. Two of seven surgical cases available for follow-up were euthanized as a result of serosal adhesions. These results suggest that if surgical treatment is required, techniques to reduce adhesion formation, such as minimal handling of the bowel and topical carboxymethylcellulose during bowel manipulation, should be practiced.

**Vascular Lesions**

**Intramural Hematoma**

The incidence of small colon intramural or submucosal hematoma is very low, less than 1% of surgical colics. Most often the cause of the lesion is unknown, although focal ulceration with infection and iatrogenic trauma have each been described in one horse. Although it has been stated that older horses are at an increased risk, the low number of reported cases makes this difficult to ascertain. Four of seven cases were 10 years old or younger, whereas one of seven was older than 20 years in two case series. In another report of six horses, the age range was between 9 and 18 years. The intramural hematoma causes obstruction of the small colon lumen initially with subsequent ischemic necrosis of the bowel wall leading to septic peritonitis, endotoxemia, circulatory shock, and death if not treated.
Horses are often presented with varying degrees of abdominal pain that may become acutely severe. Heart rate is mildly to markedly elevated. Rectal palpation findings may reveal gas distention of the large intestine, decreased fecal content, and occasionally dark or clotted blood. In some cases, a solid mass is palpable per rectum. During surgical exploration, the lesion is readily identified as a soft, dense, circumscribed mass occupying the bowel lumen and attached to the bowel wall. The lesion has been described as involving between 20 and 55 cm in a series of six cases. Treatment is surgical resection and anastomosis. The prognosis can be good if the lesion is located in a region that allows its complete resection, and if surgical intervention occurs before transmural necrosis or bowel rupture leads to bacterial peritonitis. Colostomy should be considered if the lesion is too far caudal to allow exteriorization.

Mesocolic Rupture
The incidence of rupture of the mesocolon has been reported to be between 0.4% and 2.5% in horses undergoing exploratory laparotomy for colic. Rupture of the mesocolon leading to segmental ischemic necrosis of the small colon has been described as a complication of parturition in the mare. The vigorous reflex kicking and head movement of the foal that allows it to rotate into a dorsal position for delivery is thought to mechanically tear the mesentery that is caught between the uterus and dorsal body wall. Mesocolon rupture may also occur as a consequence of type III or IV rectal prolapse, often associated with tenesmus after parturition. If more than 30 cm of the rectum prolapses, ischemic necrosis of the rectum and small colon should be expected from disruption of the mesocolon and vascular arcade. Mares are typically middle aged and pluriparous. Foaling may have been normal or required assistance.

Time from foaling to the onset of colic is variable, ranging from 0 to 24 hours, with referral 12 to 48 hours later. The severity of abdominal pain varies greatly from no demonstrable pain to severe pain. The initial mild abdominal discomfort may be incorrectly attributed to uterine involution, delaying the recognition of a surgical problem. There is a consistent lack of feces. Rectal examination findings vary from normal to feed-impacted small colon with gas-distended large intestine. Peritoneal fluid has an elevated protein and nucleated cell content, with intra-abdominal hemorrhage seen in some cases. The decision for surgery is often based on duration of pain and peritoneal fluid changes. Laparoscopy can be useful in making the diagnosis and determining the extent of damage.

Treatment consists of surgical resection and anastomosis if viable proximal and distal small colon is accessible for the anastomosis. A temporary colostomy to divert feces away from the compromised bowel has been suggested to facilitate healing if an anastomosis can be performed. In most cases, tears resulting from rectal prolapse do not have sufficient viable distal small colon to allow for an anastomosis. A permanent colostomy is required in these cases. Often the prognosis is poor as a result of the extent of the tear or the delay in surgical intervention.

Nonstrangulating Infarction
Nonstrangulating infarction of the small colon is uncommon, perhaps because the majority of the blood supply to the small colon is through the caudal mesenteric artery, which is not a common site of occlusive verminous arteritis. In a review of 38 cases of small colon obstruction, the three cases with nonstrangulating infarction of the small colon showed no evidence of verminous arteritis. Clinical signs are similar to those described previously for mesocolic rupture, with mild intermittent abdominal pain of 10 to 72 hours' duration. Peritoneal fluid most likely has an elevated protein concentration and nucleated cell counts. Treatment consists of surgical resection and end-to-end anastomosis. Since, in most cases, viable proximal and distal small colon is accessible for the anastomosis, the prognosis should be good as long as surgical intervention occurs before ischemic necrosis of the infarcted segment causes septic peritonitis. When the infarcted segment cannot be exteriorized through a laparotomy, a colostomy or transrectal exteriorization followed by rectocolostomy should be considered.

Strangulating Lesions
Strangulating Lipomas
Strangulating lipomas of the small colon account for approximately 11% of small colon disease. They are most commonly seen in horses older than 15 years and are not reported in horses younger than 8 years. Geldings may be at an increased risk compared with mares and stallions. Ponies have been reported to be at increased risk. It is not uncommon for lipomas to form in the mesentery of the small colon because of the amount of fat it contains. However, unlike in the small intestine, many do not cause clinical problems, as the thickness and diameter of the small colon wall and the fecal balls within its lumen prevent the pedunculated lipoma from encircling and strangulating the bowel. In horses with strangulating pedunculated lipomas, approximately 7% are located in the small colon, whereas 93% are located in the small intestine. In some cases, the pedunculated lipoma encircles the small colon, causing obstruction without significant vascular impairment.

Although some horses with small colon strangulating lipomas demonstrate signs of severe colic, others do not show the amount of abdominal pain commonly seen with strangulating lesions involving other areas of the gastrointestinal tract. Peritoneal fluid changes include increased nucleated cell count and protein concentration. The predominant abnormal rectal findings are gas distention of the large colon and cecum with absence of fecal balls in the small colon. In certain cases, the clinician’s hand can be advanced to the area of the constriction. A fibrous band encircling the colon may be palpable. Transrectal ultrasonography may indicate increased thickness of the small colon wall with intestinal distention. Treatment consists of surgical removal of the lipoma with resection and anastomosis of any compromised small colon.

Volvulus, Herniation, Intussusception
Volvulus of the small colon is a very rare cause of colic, most likely as a result of its fixed extremities and its relatively
short length. The firm fecal balls within the lumen and its fatty mesentery may also prevent the small colon from twisting around its mesentery. Adhesions and abscesses have been associated with small colon volvulus. Herniation of the small colon, which may result in a strangulating obstruction, has been reported to occur with umbilical, inguinal, and body wall hernias, as well as through omental, mesenteric, uterine, vaginal, broad ligament, and gastroplenic ligament tears. Intussusception not associated with rectal prolapse has been reported in foals and one broodmare. If the point of invagination is at the distal end of the small colon, the intussusception may protrude from the anus. In this case, a finger can be inserted between the protruding bowel and the anal sphincter and advanced cranially until reaching a blind end.

Clinical signs are similar to those seen with strangulating lipomas of the small colon. There is usually a sudden onset of colic, although the clinical course may be more prolonged than seen with strangulating lesions of the more proximal gastrointestinal tract. Rectal examination reveals lack of feces and gas distention of the large colon. In some cases, the small colon is under considerable tension, limiting the rectal examination. Blood staining of feces may be present with an intussusception. Peritoneal fluid is often serosanguineous in color, with increased nucleated cell count and protein concentration.

Treatment involves surgical resection and anastomosis through a ventral midline laparotomy. Rectocolostomy has been described as a treatment for distal intussuscipent small colon protruding through the anus in an 8-week-old foal. In this transectral procedure, an encircling incision was made in the outer layer of the intussusception 4 cm caudal to the anal sphincter. Ligatures were placed around the mesenteric vessels. Continuity was restored by a colorectostomy using simple-interrupted sutures of 2-0 polyglactin.

Atresia Coli

Atresia coli is a very rare condition in the foal, involving the large, transverse, or small colon. It should not be confused with ileocolonic aganglionosis, seen in the recessive lethal white foal syndrome of the overo white foal. In the lethal white syndrome, which is always fatal, foals are born with no pigment (except for the eyes) and have stenotic colons that have thin muscular walls and few myenteric plexuses, leading to megacolon and death. Although the cause of atresia coli remains unknown, it has been proposed that a vascular injury during fetal development leads to focal ischemic necrosis of the intestinal segment. The segment of small colon where the enterotomy is to be made in the antimesenteric teniae. Enterotomies in this region were performed to provide access to the lesion. The preferred location for the enterotomy is a longitudinal incision on the antimesenteric teniae. Enterotomies in this location have been found to be stronger, to allow easier apposition, to develop less intraoperative hemorrhage, and to maintain an increased postoperative lumen size compared with enterotomies that do not involve the teniae.

The segment of small colon where the enterotomy is to be performed is exteriorized and draped separately from the abdomen and the rest of the gastrointestinal tract. Intestinal clamps or Penrose drains are placed proximal and distal to the enterotomy site to prevent spillage of fecal material.

Neoplasia

Small colon neoplasia is very rare. Lipomas have been discussed previously. A leiomyoma of the small colon found during exploratory laparotomy for a large colon displacement was successfully treated in a 4-year-old Thoroughbred with resection and anastomosis. Leiomyomas have been reported to cause an intussusception in the small colon, and a lymphoma causing perforation of the small colon has been reported.

Miscellaneous Conditions

Other conditions of the small colon that have been reported are partial obstruction by an abdominal testicular teratoma, obstruction from an ovarian pedicle in a foal, and in three mares, obstruction from a granulosa cell tumor, and secondary chronic idiopathic intestinal pseudo-obstruction (myenteric ganglionitis) in a 4-year-old Standardbred causing recurrent impaction.

Surgical Procedures

Small colon enterotomy: Small colon enterotomy is indicated to remove various types of intraluminal obstruction of the small colon, such as fecal impactions, enteroliths, fecaliths, and foreign bodies. In most cases, a ventral midline celiotomy is performed to provide access to the small colon. However, in select cases, such as a fecalith or foreign body, if there are financial constraints, a flank incision may provide adequate access to the lesion. The preferred location for the enterotomy is a longitudinal incision on the antimesenteric teniae. Enterotomies in this location have been found to be stronger, to allow easier apposition, to develop less intraoperative hemorrhage, and to maintain an increased postoperative lumen size compared with enterotomies that do not involve the teniae.

The segment of small colon where the enterotomy is to be performed is exteriorized and draped separately from the abdomen and the rest of the gastrointestinal tract. Intestinal clamps or Penrose drains are placed proximal and distal to the enterotomy site to prevent spillage of fecal material.
during the enterotomy. Stay sutures are placed approximately 1 cm from the ends of the enterotomy incision. The incision is made sharply with a #10 scalpel blade. A two-layer closure is performed using a full-thickness simple-continuous pattern followed by a seromuscular inverting pattern with 2-0 polyglactin 910, taking care to invert a minimal amount of tissue.

In some horses, the intraluminal obstruction, typically an enterolith, is lodged in the proximal small colon where the short mesocolon prevents adequate exteriorization, increasing the risk of peritoneal contamination during the enterotomy. If retropulsion into the right dorsal colon is not feasible, a modified teniotomy can be performed and may facilitate normograde movement of the obstruction to a more accessible location.\textsuperscript{217} In this technique, the large colon is first evacuated to decrease fecal material proximal to the obstruction. The site of obstruction is isolated from the rest of the abdominal cavity with sterile moistened drapes. Stay sutures are placed within the antimesenteric tenia proximal to the site of obstruction and 30 to 15 cm distal to the site. Fluid and ingesta are stripped away from the area. Topical 2% lidocaine can first be applied to reduce muscular spasm. A 1-cm longitudinal seromuscular incision is made with a scalpel blade in the antimesenteric tenia 10 to 15 cm aboral to the obstruction. The seromuscular incision is continued orally to the widest part of the obstruction using Metzenbaum scissors. Gentle pressure applied through the wall of the small colon is used to advance the obstruction to a more accessible location, where the mucosa is incised and the obstruction removed. The enterotomy incision is closed as described earlier. This technique is most suitable for obstructions with a smooth surface, such as enteroliths, making them more likely to move distally. In one report, enteroliths were moved distances of 4 to 15 cm.\textsuperscript{142}

**Small colon resection and anastomosis:** Several techniques have been described for small colon anastomosis. These include hand-sutured single-layer end-to-end anastomosis, hand-sutured double-layer end-to-end anastomosis, and triangulated end-to-end evertting stapled anastomosis.\textsuperscript{265-267} A two-layer technique consisting of a full-thickness appositional pattern oversewn with a partial-thickness continuous inverting layer has less risk for dehiscence, peritonitis, and adhesion formation than the hand-sutured single-layer and stapled closure. As well, it creates less tissue inversion than a double inverting pattern, decreasing the chances of postoperative impaction at the anastomosis site.\textsuperscript{265-267}

The vascular arcade supplying the compromised small colon is traced back to normal bowel. The marginal artery at the oral and anal side of the lesion is identified and isolated within the mesenteric fat and is triple-ligated. To prevent inadvertent puncture of a vessel to be ligated with the pointed taper needle, especially if the vessel is partly covered by fat, the needle can be advanced around the vessel with its back first, since this blunt end avoids vessels (Fig. 36-29). Once the suture is placed around the vessel, because firm tightening cuts through the fat tissue surrounding the vessel. The vessels are transected with the vessels remaining in situ double-ligated. Vessels supplying the intestine to be removed are triple-ligated and sectioned. The ingesta is milked out of the segment of small colon to be resected and Penrose drains or intestinal clamps are positioned approximately 10 to 20 cm proximal and distal to the resection area to occlude the bowel lumen and decrease contamination from luminal contents during the resection. Doyen intestinal clamps are placed across the descending colon at the oral and anal extent of the resection, angled at approximately 30 degrees from perpendicular so that the length of the small colon at the antimesenteric angle is shorter than the intestine at the mesenteric angle (Fig. 36-30). This should improve blood supply to the antimesenteric border and increase the luminal size of the anastomosis compared with perpendicular transection angles. Moistened sterile drapes are used to isolate this region from the abdomen and adjacent bowel. A scalpel is used to sharply transect the colon, cutting adjacent to the

![Figure 36-29. Using the blunt back end of a taper-point needle to place a ligature around a semi-hidden (by fat) mesenteric vessel allows safe placement of a ligature around vessels without inadvertent trauma to the vessel.](image1)

![Figure 36-30. Penrose drains or intestinal clamps are positioned approximately 10 to 20 cm proximal and distal to the resection area to occlude the bowel lumen and decrease contamination from luminal contents during the resection (not shown). Doyen intestinal clamps are placed across the descending colon at the oral and anal extent of the resection, angled at approximately 30 degrees from perpendicular so that the length of the small colon at the antimesenteric angle is shorter than the intestine at the mesenteric angle. A scalpel is used to sharply transect the colon, cutting adjacent to the Doyen intestinal clamps and using them to guide a straight transection line.](image2)
Doyen intestinal clamps and using them to guide a straight transaction line. The proximal and distal segments are aligned with stay sutures placed at the mesenteric and antimesenteric borders. A slight rotation of the two segments of bowel offsets the mesocolon attachments, allowing a more secure closure at the mesenteric border. The first layer placed is a full-thickness simple-continuous pattern tied at the mesenteric and antimesenteric angles, or a simple-interrupted pattern using no. 0 or 2-0 absorbable suture material. The second layer is a partial-thickness inverting layer using 2-0 absorbable suture interrupted at 180 degrees. The mesentry is closed with a simple-continuous pattern.

POSTOPERATIVE CARE AND COMPLICATIONS
Because of the high concentration of both aerobic and anaerobic bacteria, broad-spectrum antimicrobial coverage with potassium penicillin (22,000 IU/kg, twice a day IV), gentamicin sulfate (6.6 to 8.8 mg/kg, once a day IV), and metronidazole (15 mg/kg, twice a day IV) is recommended. If the bowel is healthy and the surgical procedure is performed with minimal and contained contamination, perioperative (for 24 hours) use of antibiotics can be appropriate. More extended postoperative administration (therapeutic course) of antibiotics (for 5 to 10 days) should be chosen if the horse has compromised bowel, has any signs of peritonitis, or has acquired abdominal contamination during the surgical procedure. Adjunctive antiendotoxin therapy, such as polymyxin B and hyperimmune serum, should be considered in horses with signs of endotoxemia or septicemia.

Postoperative complications with small colon surgery are dehiscence, stricture and adhesion formation, and impaction at the enterotomy or anastomosis. Other complications, such as peritonitis, diarrhea, thrombophlebitis, and laminitis, are associated with endotoxemia and septicemia. It has been proposed that several factors specifically affect small colon surgery adversely compared with surgery of other areas of the gastrointestinal tract. These are the high concentration of collagenase in the small colon, the high concentration of bacteria (including anaerobic bacteria), the mechanical stress placed on the surgical site by firm fecal balls passing over the incision, and the poor vascular supply. Other authors have questioned some of these assumptions. One study has shown that the small colon vascular arcade system has adequate collateral blood supply. If the lesion is in an area that allows adequate surgical access, the blood supply should not be a limiting factor. The small colon is at risk for postoperative impactions because of the character of the feces and the size of the lumen. Impaction places further stress on an enterotomy or anastomosis site, increasing the risk of dehiscence. Although evacuation of the large colon decreases the risk of this occurring, postoperative feeding should also be carefully controlled to further decrease the risk of impaction at the enterotomy or anastomosis site. Reports suggest that with good surgical technique and attention to postoperative management (such as careful reintroduction to feed), horses have a good prognosis after small colon surgery.

HMPAO) labeled white blood cells for the diagnosis of right dorsal ulcerative colitis in two horses, Vet Radiol Ultrasound 2000;41:360.

The rectum is approximately 30 cm long in an adult horse and extends from the pelvic inlet to the anus. The distance from the anus to the peritoneal reflection is highly variable and is shorter in young horses and in horses with little body fat. The peritoneal part of the rectum is attached dorsally by the mesorectum, which is a continuation of the mesocolon. The retroperitoneal part of the rectum forms a dilation called the rectal ampulla, which has thick longitudinal muscle bundles. The anal canal is approximately 5 cm long and is enclosed by the internal anal sphincter, which is a thickening of the circular smooth muscle, and the external anal sphincter, which is composed of striated muscle. The levator ani muscle arises from the ischiatic spine and sacrotuberal ligament and ends under the external anal sphincter. Its action overcomes the tendency of the anus to prolapse during defecation.

RECTAL TEARS
Rectal tears caused by palpation per rectum commonly result in malpractice claims against veterinarians in the United States. However, the standard of care for a horse that has incurred a rectal tear is also subject to claims for negligence, and this is an area in which most veterinarians leave themselves vulnerable to malpractice suits. Copious lubrication of the hand and forearm and adequate restraint of the horse, including sedation if necessary, should be regarded as the minimal measures required to prevent iatrogenic rectal tears. Once a rectal tear is suspected, the veterinarian must assess the tear for severity, inform the owner about the nature of the problem (without making statements that imply admission of guilt or responsibility for payment), and apply appropriate treatment, including referral. Failure to follow these guidelines will weaken a veterinarian’s legal defense. The veterinarian should also contact his or her liability insurance company promptly.

Causes
Most rectal tears result from rupture of the rectal wall as it contracts around the examiner’s hand or forearm rather than from penetration with the finger tips. To avoid a tear, no attempt should be made to force against straining or a peristaltic wave, and intra-abdominal structures should be palpated only when the hand has been inserted beyond the contraction and then withdrawn to that level. Special precautions should be taken with Arabian horses, ponies, small breeds, horses that have had a previous rectal tear or injury, horses that are unaccustomed to palpation per rectum, fractious horses, and horses with colic.

Less common causes of rectal tears are enemas, meconium extraction by forceps, sadism, dystocia, animal bites, chronic impaction at a stricture, misdirection of a stallion’s penis, spontaneous tears, rectal thrombosis, and sand impactions. In one report of five horses with idiopathic tears, four presented with colic, and the tear developed in one horse during a lameness examination. Idiopathic tears tend to be transversely oriented.

Classification and Locations
Rectal tears are divided into four grades based on severity. In grade I tears, only the mucosa and submucosa are torn. In grade II tears, only the muscular layer is disrupted, causing the mucosa and submucosa to prolapse through the defect and create a site for fecal impaction. These are rare (3 of 85 tears in one series), but chronic impactions in the diverticulum may necessitate euthanasia. Grade III tears involve all layers except the serosa (grade IIIa) or mesorectum and retroperitoneal tissues (grade IIIb). It is not unusual for grade IIIb tears to pack with feces and produce a large plane of dissection cranially and dorsally, even approaching the left kidney. The feces packed in retroperitoneal spaces can be a source of bacterial contamination of the peritoneal cavity (Fig. 37-1). A grade IV tear involves all layers and is the most serious, since it allows fecal contamination of the peritoneal cavity. Most tears involve the dorsal aspect of the rectum, are located 15 to 55 cm from the anus, and occur parallel to the longitudinal axis. Distance from the anus is not a reliable indicator of tear location relative to the retroperitoneal reflection.

Most tears involve the dorsal aspect of the rectum, are located 15 to 55 cm from the anus, and occur parallel to the longitudinal axis. Distance from the anus is not a reliable indicator of tear location relative to the retroperitoneal reflection.
Clinical Signs and Diagnosis

Early diagnosis is essential for successful treatment and to avoid legal repercussions. When a tear occurs, the veterinarian may feel a sudden release of pressure or suddenly be able to directly palpate abdominal organs. Alternatively, the examiner may not sense the torn rectum. A rectal tear should be suspected if a large amount of blood is evident on the rectal sleeve on withdrawal of the hand or if the rectum suddenly relaxes while the horse is straining. Within 2 hours after a rectal tear occurs, the horse usually shows signs of peritonitis and endotoxic shock. Signs of colic are also present initially, but these soon give way to depression. Feces can be hemorrhagic initially and defecation can be accompanied by straining. Idiopathic tears are usually presented as colic of variable duration, and, because there is no reason to suspect a rectal tear, referral can be delayed.

Before examination of the tear, straining and rectal contractions are stopped with epidural anesthesia or xylazine (0.1 to 0.2 mg/kg body weight IV), alone or in combination with butorphanol tartrate (0.1 mg/kg IV). Butylscopolamine bromide (Buscopan), 20 mg IV, relaxes the rectum and small colon very well, allowing examination of rectal tears. A lidocaine enema can be given (12 mL of 2% lidocaine in 50 mL of tap water) or lidocaine jelly applied to the rectal mucosa before inspecting the tear digitally or through a tube speculum or endoscope. For digital palpation, the examiner can use the bare hand or wear a surgeon’s glove and apply copious lubrication with a water-soluble gel. Because the abundant mucosal folds tend to obscure the rectal tear, more information can be gained from careful palpation than by visual inspection. Failure to accurately grade a tear can cause inappropriate treatment selection. A grade I tear can feel like a flap of mucosa, but a grade III tear can cause inappropriate treatment selection.

Initial Treatment

First aid is applied as soon as the diagnosis is made and includes (1) reduction of activity of the rectum, (2) gentle removal of feces from the tear and rectum, (3) treatment of septic shock and peritonitis, and (4) administration of epidural anesthesia and packing of the rectum.

Flunixin meglumine (1.1 mg/kg every 24 hours IV) and antibiotics, such as sodium or potassium penicillin (22,000 IU/kg of body weight every 6 hours IV), gentamicin (6.6 mg/kg every 24 hours IV), and metronidazole (15 mg/kg every 6 hours PO) should be administered and continued as indicated. Intravenous fluids are required to treat shock. Antibiotics and laxatives may be sufficient treatment for grade I and II tears, with daily inspection and careful evacuation of the rectum as needed.

Rectal packing can prevent conversion of a grade III to a grade IV tear and can protect the tear from fecal contamination in the interval before definitive treatment is applied. The packing material of choice is a 3-inch stockinette filled with 0.25 kg of moistened rolled cotton, sprayed with povidone-iodine, and lubricated with surgical gel. The packing should fill the rectum without distention to a point 10 cm proximal to the tear, taking care not to pack the tear itself. The anus is subsequently closed with towel clamps or a pursestring suture, and the epidural anesthetic is repeated as necessary to decrease straining.

Surgical Management

A temporary indwelling rectal liner and colostomy divert feces away from grade III and grade IV rectal tears and thereby prevent contamination and impaction of perirectal tissues, enlargement of the tear, and progression of peritonitis. Each can be combined with direct suture repair and thereby used to protect the suture line during healing.

Temporary Indwelling Rectal Liner

A temporary indwelling rectal liner can be constructed by gluing a palpation sleeve with the hand portion removed, or the plastic cover for an arthroscope camera, to a 5-cm-diameter and 7.5-cm-long rectal prolapse ring with holes through which Dacron loops are laced. With the horse anesthetized in dorsal recumbency, an unscrubbed assistant passes the well-lubricated ring and liner through the anus so the surgeon can guide it through a ventral midline celiotomy, cranial to the tear but far enough caudally that the sleeve does not retract into the rectum when the horse stands (Fig. 37-2). A circumferential suture of size 3 surgical gut is placed tightly around the small colon over the central groove of the prolapse ring, and four equidistant retention sutures (2-0 polyglycolic acid) are placed to incorporate the circumferential suture, all layers of the rectal wall, and the Dacron loops in the modified prolapse ring. Then, the serosal surface is apposed over the circumferential suture with a Lembert pattern. The large colon is emptied through a pelvic flexure enterotomy, and the small colon is emptied by flushing with a hose directed through the ring and liner from the anus.

The circumferential suture will cut through the rectal wall and allow passage of the ring and liner in feces within approximately 9 to 12 days, by which time the apposed colon walls will have healed. The four retention sutures help maintain the ring in a coaxial relationship with the small colon so that it does not twist and obstruct the lumen. Horses are usually cross-tied to prevent them from lying down, which would allow the sleeve to retract forward. Failures have been caused by tearing of the sleeve,
retraction of the sleeve into the rectum uncovering the tear, and formation of a rectoperitoneal fistula. 5,19
